

ABSTRACT

SEARCH FOR CHARGED HIGGS BOSONS IN THE $\tau + \ell$ FINAL STATE WITH 139 fb^{-1} OF pp COLLISION DATA AT $\sqrt{s} = 13 \text{ TeV}$ WITH THE ATLAS EXPERIMENT

Elliot Wesley Parrish, Ph.D.

Dhiman Chakraborty and Jahred Adelman, Director

This dissertation uses 139 fb^{-1} of pp collision data collected at a center of mass energy of $\sqrt{s} = 13 \text{ TeV}$ by the ATLAS detector to search for charged Higgs bosons decaying to a tau lepton and a neutrino ($H^\pm \rightarrow \tau^\pm \nu_\tau$) in association with a top quark. Two subchannels are defined based on the leptonic decay ($\tau + \ell$) or hadronic decay ($\tau + \text{jets}$) of the associated top quark. Parameterized Neural Networks are investigated and optimized to improve signal separation from background in both subchannels across a wide m_{H^\pm} range of 80 GeV to 3000 GeV. Expected exclusion limits at 95% confidence on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ are compared to previous observed limits.

| 3.3 Design resolution of EM and hadronic calorimeters in the ATLAS Detector.. | 37 |
| | |
| 6.1 H^\pm production mechanisms based on m_{H^\pm} , dominant H^\pm decay mode, and the main background associated with the diagram. | 62 |
| 6.2 Definitions of physics objects used in this analysis. | 63 |
| 6.3 $\tau + \text{jets}$ and $\tau + \ell$ signal region definitions. | 65 |
| 6.4 For each H^\pm mass the generator xcross-section ($\sigma \times BR(H^\pm \rightarrow \tau^\pm \nu_\tau)$) is given, as well as the number of generated events for both $\tau + \ell$ and $\tau + \text{jets}$ subchannels. | 67 |
| 6.5 Dominant backgrounds from prompt $\tau_{\text{had-vis}}$ and fake $\tau_{\text{had-vis}}$ candidates. . . | 68 |
| 6.6 Cross sections for the main SM background samples at $\sqrt{s} = 13$ TeV . Here, ℓ refers to the three lepton families e , μ and τ . All background cross sections are normalized to NNLO predictions, except for diboson events, where the NLO prediction is used. A '*' indicates that the quoted cross section for the sample is neglecting leptonic/hadronic branching ratios. | 68 |

|-------|--|------|
| 6.7 | Control region definitions for the $\tau + \text{jets}$ subchannel | 69 |
| 6.8 | Control region definitions for the $\tau + \ell$ subchannel | 69 |
| 6.9 | List of low level (a) and high level (b) kinematic variables used as input to the PNN in the $\tau + \ell$ subchannel. $\Delta\phi_{X,\text{miss}}$ denotes the difference in azimuthal angle between a reconstructed object X ($X = \tau, b - \text{jet}, \ell$) and the direction of the missing transverse momentum. | 79 |
| 6.10 | First grid, scanning over activation function and loss function. Binary cross-entropy was the chosen loss function, highlighted in red. | 81 |
| 6.11 | Second grid, scanning over width, depth, and dropout value. 0.1 was chosen for the dropout value, highlighted in red. | 81 |
| 6.12 | Third grid, scanning over activation function. LeakyReLU was chosen, highlighted in red. | 82 |
| 6.13 | Fourth grid, scanning over LeakyReLU α value. $\alpha = 0.05$ was chosen, highlighted in red. | 82 |
| 6.14 | Fifth grid, scanning over network width and depth. $width = 128$ and $depth = 3$ was chosen, highlighted in red. | 82 |
| 6.15 | AUCs of final HPO grid. An error of 0 corresponds to only one job k-fold finishing training due to computational limits. The LowMassAvg error takes into account difference | 83 |
| 6.16 | Average AUCs of final HPO grid. An error of 0 corresponds to only one job k-fold finishing training due to computational limits. | 83 |
| 6.17 | Effect on the shape variation and the yields of systematic uncertainties associated with the data-driven fake factor method, used to estimate the $j \rightarrow \tau$ background in the $\tau + \text{jets}$ and $\tau + \ell$ channel. | 85 |
| 6.18 | Expected event yields for the backgrounds and a hypothetical H^\pm signal after applying all $\tau + \text{jets}$ selection criteria, and comparison with 139 fb^{-1} of data. All yields are evaluated prior to using the multivariate discriminant and applying the statistical fitting procedure. The values shown for the signal assume a charged Higgs boson mass of 170 GeV and 1000 GeV, with a cross-section times branching fraction $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ corresponding to $\tan\beta = 40$ in the hMSSM benchmark scenario. Statistical uncertainties are quoted. Systematic uncertainties to be added. | 86 |

LIST OF FIGURES

| Figure | Page |
|--|------|
| 2.1 Quarks are fundamental particles that combine to create protons or neutrons ² [1]. | 4 |
| 2.2 The Higgs potential defined in 2.2 with $\mu^2 < 0$ [5] | 9 |
| 2.3 The distributions of the invariant mass of diphoton candidates after all selections for the combined 7 TeV and 8 TeV data sample. The inclusive sample is shown in (a) and a weighted version of the same sample in (c); the weights are explained in the text. The result of a fit to the data of the sum of a signal component fixed to $m_H = 126.5$ GeV and a background component described by a fourth-order Bernstein polynomial is superimposed. The residuals of the data and weighted data with respect to the respective fitted background component are displayed in (b) and (d). [6]. | 16 |
| 2.4 Examples of leading-order Feynman diagrams contributing to the production of charged Higgs bosons in pp collisions: (a) non-resonant top-quark production prevalent in the intermediate-mass range, (b) single-resonant top-quark production that dominates at large H^\pm masses, (c) double-resonant top-quark production that dominates at low H^\pm masses. The interference between these three diagrams becomes most relevant in the intermediate-mass region. | 17 |
| 2.5 Variation of $\sigma(pp \rightarrow tbH^\pm) \times B(H^\pm \rightarrow \tau^\pm \nu_\tau)$ with the charged Higgs boson mass in pp collisions at $\sqrt{s} = 13$ TeV , for $\tan\beta$ values of 7, 20, and 40 in the hMSSM scenario. Dashed lines correspond to $B(H^\pm \rightarrow \tau^\pm \nu_\tau)$ set to 1, hence they show the dependence of $\sigma(pp \rightarrow tbH^\pm)$ with m_{H^\pm} . [8] | 17 |
| 2.6 Branching fractions of H^\pm as a function of m_{H^\pm} for (a) $\tan\beta = 10$ and (b) $\tan\beta = 50$ in the m_h^{mod+} scenario of the MSSM [9]. | 18 |
| 2.7 Exclusion limits at 95% CL on $\sigma(pp \rightarrow tbH^\pm \times B(H^\pm \rightarrow \tau^\pm \nu))[pb]$. (a) is for the $\tau+jets$ subchannel (b) corresponds to the $\tau + \ell$ subchannel and (c) is the combination of the two subchannels. [8] | 19 |
| 2.8 Exclusion limits at 95% CL on $\tan\beta$ as a function of m_{H^\pm} [8]. | 20 |

| 3.3 The CERN accelerator complex. [15] | 26 |
| 3.4 Cumulative luminosity versus time delivered to ATLAS (green), recorded by ATLAS (yellow), and certified to be good quality data (blue) during stable beams for pp collisions at 13 TeV center of mass energy in 2015-2018. The difference between the colored histograms reflects inefficiencies, especially those seen when restarting data taking [16]. | 27 |
| 3.5 The luminosity-weighted distribution of the mean number of interactions per bunch crossing for the 2015-2018 pp collision dataset at 13 TeV center of mass energy [16] | 28 |
| 3.6 A display of a candidate Z boson event from proton-proton collisions recorded by ATLAS with LHC stable beams at a collision energy of 13 TeV. The Z boson candidate is reconstructed in a beam crossing with 28 additionally reconstructed primary vertices from the minimum bias interactions. The candidate event is reconstructed in the 2μ final state. In the left display, the red lines show the path of the two muons including the hits in the muon spectrometer and the orange tracks are the remaining charged particles from the 29 vertices, with transverse momentum above 0.5 GeV. The colored squares in the lower display correspond to the position of the reconstructed vertices. The invariant mass of the two muons is 92.3 GeV [17]. | 29 |

| 4.2 A pictorial representation of a parton shower of a $t\bar{t}H$ event [28]. | 47 |
| 5.1 Cross section view of the ATLAS detector with subdetectors labeled. Various types of particles radial trajectories are shown [25]. | 49 |
| 5.2 Algorithm flow diagram for the electron and photon reconstruction [39]. | 54 |
| 5.3 A flow chart of how the particle flow algorithm proceeds, starting with track selection and continuing until the energy associated with the selected tracks has been removed from the calorimeter. At the end, charged particles, topoclusters which have not been modified by the algorithm, and remnants of topoclusters which have had part of their energy removed remain [40]. | 55 |

| Figure | Page |
|--|------|
| 5.4 Idealized examples of how the algorithm is designed to deal with several different cases. The red cells are those which have energy from the π^+ , the green have cells energy from the photons in the π^0 decay, the dotted lines represent the original topocluster boundaries with those outlined in blue having been matched by the algorithm to the π^+ , while those in black are yet to be selected. The different layers in the EM calorimeter (Presampler, EMB1, EMB2, EMB3) are indicated. In this sketch only the first two layers of the Tile calorimeter are shown (TileBar0 and TileBar1) [40] | 56 |
| 5.5 Comparison between several jet finding algorithms [41]. | 57 |
| 5.6 Schematic view of the tracks in a b -jet [43]. | 58 |
| 6.1 Signal acceptance as a function of the charged Higgs boson mass for both the $\tau + \text{jets}$ (a) and $\tau + \ell$ subchannels (b). | 65 |
| 6.2 Mass of $\tau - e$ system in the Zee control region. All systematics except for $t\bar{t}$ theory uncertainties are included. | 70 |
| 6.3 Combined FF for the $\tau + \text{jets}$ b-veto $m_T > 100$ control region, $\tau + \text{jets}$ signal region, $\tau + \text{electron(muon)}$ with same-sign control region and the $\tau + \ell$ signal region. Error bars represent systematic uncertainties of the method. | 72 |
| 6.4 Comparison between the predicted and the measured E_T^{miss} distributions in various control regions defined for the $\tau + \text{jets}$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction. | 73 |
| 6.5 Comparison between the predicted and the measured E_T^{miss} distributions in various control regions defined for the $\tau + \ell$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction. | 74 |
| 6.6 Comparison of performance of an optimized BDT and an unoptimized PNN on expected limits on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ in the $\tau + \text{jets}$ (a) and $\tau + \ell$ (b) signal regions. | 75 |

| Figure | Page |
|--|------|
| 6.7 <i>Left</i> , individual networks with input variables (x_1, x_2) , each trained with examples with a single value of some parameter $\theta = \theta_a, \theta_b$. The individual networks are purely functions of the input variables. Performance for intermediate values of θ is not optimal nor does it necessarily vary smoothly between the networks. <i>Right</i> , a single network trained with input variables (x_1, x_2) as well as input parameter θ ; such a network is trained with examples at several values of the parameter θ [53]. | 77 |
| 6.8 The k-fold method for $k = 5$ [57]. | 77 |
| 6.9 Expected limits comparing a set of high level variables and low level variables with various depths in the PNN architecture. X layers refers to the number of layers in the PNN. | 80 |
| 6.10 Final model AUC for each mass point. Individual points correspond to the AUC average over 5 kfolds. | 84 |
| 6.11 LeakyReLU activation function. The associated hyperparameter α is the slope of the negative portion of the function. | 85 |
| 6.12 PNN score distributions in the signal region of the $\tau+\text{jets}$ channel, for the six charged Higgs boson mass parameters. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty bands include all statistical and systematic uncertainties. The normalization of the signal (shown for illustration) corresponds to the integral of the background. | 89 |
| 6.13 PNN score distributions in the signal region of the $\tau+e$ sub-channel, for the six charged Higgs boson mass parameters. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty bands include all statistical and systematic uncertainties. The normalization of the signal (shown for illustration) corresponds to the integral of the background. | 90 |
| 6.14 PNN score distributions in the signal region of the $\tau+\mu$ sub-channel, for the six charged Higgs boson mass parameters. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty bands include all statistical and systematic uncertainties. The normalization of the signal (shown for illustration) corresponds to the integral of the background. | 91 |

| Figure | Page |
|--|------|
| 6.15 Expected 95% CL exclusion limits on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ as a function of the charged Higgs boson mass in 139 fb^{-1} of pp collision data at $\sqrt{s} = 13\text{ TeV}$ in the $\tau + \text{jets}$ signal region (a), $\tau + \ell$ signal region (b), and the combination of the $\tau + \text{jets}$ and $\tau + \ell$ signal regions (c). In the case of the expected limits, one- and two-standard-deviation uncertainty bands are also shown. As a comparison, the expected exclusion limits obtained with the dataset collected in 2015 and 2016 [8] are also shown. | 92 |
| A.1 TileCal calibration checks within the readout chain [20]. | 97 |
| A.2 Average response variation from the beginning of Run-2 of TileCal cell A13 is shown [60]. | 98 |
| B.1 Fake factors parameterized as a function of p_T^τ and the number of charged τ decay products (1-prong and 3-prong) obtained in the multi-jet and W+jets CRs. The errors shown represent the statistical uncertainty. | 100 |
| B.2 Corrected α_{MJ} values for the $\tau_{\text{had-vis}} + \text{jets}$ b-veto $m_T > 100$ control region, $\tau_{\text{had-vis}} + \text{jets}$ signal region, $\tau_{\text{had-vis}} + \text{electron(muon)}$ with same-sign control region and the $\tau_{\text{had-vis}} + \text{lepton}$ signal region. Error bars represent uncertainties due to α_{MJ} fitting using template-fit method. | 100 |
| B.3 Estimation of α_{MJ} in the $\tau_{\text{had-vis}} + \text{jets}$ signal region for $p_T \leq 60\text{ GeV}$ 1-prong $\tau_{\text{had-vis}}$ candidates. CHAPTER 1

INTRODUCTION

Science has long sought to provide an explanation to the most fundamental questions. The field of particle physics tries to answer the question of “What are we made of?” The Standard Model (SM) of particle physics is an attempt at combining all of the fundamental forces and particles into one mathematically based theory. The SM has been rigorously tested and for the most part, holds up except for a few key issues. To name a few of these issues: the absence of gravity in the theory, no candidate for dark matter, neutrino masses, and the matter-antimatter asymmetry of the universe.

There are many Beyond the Standard Model (BSM) theories that address these issues and more. A common theme of these models is an extended Higgs sector, meaning more Higgs boson-like particles. This dissertation focuses on a search for an additional Higgs boson that carries electromagnetic charge, H^\pm . The search is performed on data collected with the ATLAS detector on the LHC at Conseil Européen pour la Recherche Nucléaire (CERN) in Geneva, Switzerland.

A theoretical motivation is given in Chapter 2 followed by a detailed explanation of the LHC and the ATLAS detector in Chapter 3. Simulation of particle collisions and the reconstruction of both simulated and actual data is detailed in Chapters 4 and 5 respectively. Chapter 6 provides a thorough description of the search for the H^\pm in the $\tau^\pm\nu_\tau$ final state. Lastly future works are discussed in Chapter 7.

A considerable amount of the author’s time in the Ph.D. program was dedicated towards the search described in this dissertation and acting as the Data Quality Co-Coordinator for the hadronic calorimeter within the ATLAS Collaboration. In addition, the author assisted

on various projects within the hadronic calorimeter group including two test beams and maintenance of the calorimeter within the larger ATLAS detector.

CHAPTER 2

THEORY

In this chapter, the theoretical motivation of a search for $H^\pm \rightarrow \tau^\pm \nu_\tau$ is described. A review of the Standard Model (SM) of particle physics is laid out, followed by a brief overview of Supersymmetry (SUSY) focusing on the Minimal Supersymmetric Standard Model (MSSM). Finally, the Type II 2-Higgs Doublet Model (2HDM) relation to the H^\pm production cross section and subsequent branching ratio into SM particles is described as motivation for the choice of studying $H^\pm \rightarrow \tau^\pm \nu_\tau$.

2.1 The Standard Model

The SM of particle physics is a Quantum Field Theory (QFT) that describes all known matter and forces¹. The SM describes forces as exchanges of particles called bosons and is described in detail in Section 2.1.2. These interactions occur between fundamental particles called fermions that comprise the known matter of the universe. Figure 2.1 shows how fermions called quarks are the building blocks of nucleons, and thus atoms.

2.1.1 Particles

The particles that make up the SM are defined by their properties, or quantum numbers. These quantum numbers are used to categorize particles into various types. Intrinsic angular

¹Notably, the SM does not describe gravity.

²As well as other objects all called hadrons.

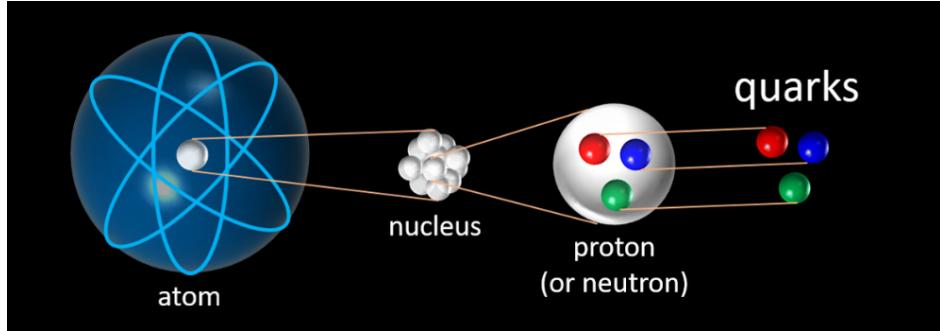

Figure 2.1: Quarks are fundamental particles that combine to create protons or neutrons²[1].

momentum charge, or spin, is the first quantum number that separates particles into fermions or bosons. Fermions are those that carry half-integer spin, and thus obey Fermi-Dirac statistics, while bosons carry full integer spin values and obey Bose-Einstein statistics.

2.1.1.1 Fermions

The matter encountered in everyday life is comprised of fermions. Fermions are subdivided into two groups, quarks and leptons. The quarks participate in the strong interaction via their color charge. Quarks cannot exist as an isolated particle and thus combine into hadrons in a process called hadronization; the bound states they form are colorless. The proton and neutron are examples of hadrons. Hadrons, quarks, and their interaction with the strong force is detailed in Section 2.1.2.3. Leptons carry no color charge and therefore do not participate in strong force interactions. The fermions in the SM all participate in the electroweak interaction. However, the electromagnetic interaction is limited to those fermions that carry an electromagnetic charge. Section 2.1.2.2 describes the electroweak interaction in detail.

Fermions can then be further divided into three generations, each lepton has an electrically neutral weak force partner in the form of a neutrino. Table 2.1 lists all the SM fermions and

their properties. Every particle has a partner with identical properties except for an opposite Electromagnetism (EM) charge. These partners are called antimatter and are denoted with a bar above the particle symbol (u, \bar{u}).

Table 2.1: Standard Model fermions and their properties [2]

| | 1 st Generation | 2 nd Generation | 3 rd Generation | Spin | EM Charge | Color | Mass |
|---------|-------------------------------|-------------------------------|-------------------------------|---------------|----------------|-------|---|
| Quarks | Up (u) | Charm (c) | Top (t) | $\frac{1}{2}$ | $+\frac{2}{3}$ | ✓ | $m_u = 2.16^{+0.49}_{-0.26} \text{ MeV}$ $m_c = 1.27 \pm 0.02 \text{ GeV}$ $m_t = 172.76 \pm 0.30 \text{ GeV}$ |
| | Down (d) | Strange (s) | Bottom (b) | $\frac{1}{2}$ | $-\frac{1}{3}$ | ✓ | $m_d = 4.67^{+0.48}_{-0.17} \text{ MeV}$ $m_s = 93^{11}_{-5} \text{ MeV}$ $m_b = 4.18^{0.03}_{-0.02} \text{ GeV}$ |
| Leptons | Electron (e^-) | Muon (μ^-) | Tau (τ^-) | $\frac{1}{2}$ | -1 | X | $m_{e^-} = 0.51 \text{ MeV}$ $m_{\mu^-} = 105.65 \text{ MeV}$ $m_{\tau^-} = 1776.86 \pm 0.12 \text{ MeV}$ |
| | Electron Neutrino (ν_e) | Muon Neutrino (ν_μ) | Tau Neutrino (ν_τ) | $\frac{1}{2}$ | 0 | X | $m_{\nu_e} < 1.1 \text{ eV}$ $m_{\nu_\mu} < 0.19 \text{ MeV}$ $m_{\nu_\tau} < 18.2 \text{ MeV}$ |

2.1.1.2 Bosons

Bosons are colloquially referred to as force-carriers in that the fundamental forces act via exchanging gauge bosons. This means that each force has associated boson(s) which is described by a field theory. The electroweak QFT is more complicated, and is described in detail in section 2.1.2.2. Table 2.2 lists the SM bosons³, their associated field theory and properties.

³excluding the Higgs

Table 2.2: Standard Model bosons and their properties [2]

| Field Theory | Boson | Spin | EM Charge | Color | Mass |
|-------------------------------|---------------------|------|-----------|-------|--------------------------|
| Quantum Chromodynamics (QCD) | Gluon (g) | 1 | 0 | ✓ | 0 |
| Quantum Electrodynamics (QED) | Photon (γ) | 1 | 0 | X | $< 1 \times 10^{-18}$ eV |
| Electroweak Theory | W^\pm | 1 | ± 1 | X | 80.379 ± 0.012 GeV |
| | Z^0 | 1 | 0 | X | 91.1876 ± 0.0021 GeV |

2.1.2 Interactions

The SM is based upon conservation laws. These conversation laws are what dictate the allowed interactions of matter. Lepton generation number⁴, electric charge, color charge, 4-momentum ($p = (E, \vec{p})$), and angular momentum are all conserved in the SM. In strong interactions baryon number⁵ ($B = \frac{1}{3}(n_q - n_{\bar{q}})$) is also conserved.

2.1.2.1 Quantum Electrodynamics

The electromagnetic force is governed by the QFT known as Quantum Electrodynamics (QED). This force is mediated by the photon, γ , a massless boson with EM charge 0. The EM force only affects, meaning the photon only interacts with charged particles including all quarks and the e , μ , and τ leptons.

2.1.2.2 Electroweak Interaction

The weak force is most often seen in nuclear decays and is mediated by the W^\pm and Z^0 bosons. Due to the relatively large mass of these bosons, the weak force has a very limited

⁴Ignoring neutrino oscillations

⁵Here, n_q and $n_{\bar{q}}$ are the number of quarks and antiquarks that comprise the baryon.

range. The weak force interacts via the quantum number called isospin (T). The W^\pm affects the third component of isospin (T_3), thus only coupling to so called left-handed fermions. In this way, T_3 defines the “handedness”, or chirality of a particle. At energies > 100 GeV the electromagnetic and weak forces combine into the electroweak force. Isospin and another quantum number hypercharge combine to give EM charge. $Q_{EM} = T_3 + \frac{1}{2}Y_W$. Table 2.3 contains the allowed values for isospin and hypercharge (Y_W).

Table 2.3: Standard Model fermions and their Electroweak properties [2]

| | 1^{st} Generation | 2^{nd} Generation | 3^{rd} Generation | EM Charge | Y_W | | T | | T_3 | |
|---------|-------------------------------|-----------------------------|-----------------------------|----------------|----------------------|----------------------|---------------------|---------|------------------------|---------|
| Quarks | Up (u) | Charm (c) | Top (t) | $+\frac{2}{3}$ | LH $+\frac{1}{3}$ | RH $+\frac{4}{3}$ | LH $\frac{1}{2}$ | RH 0 | LH $\pm\frac{1}{2}$ | RH 0 |
| | Down (d) | Strange (s) | Bottom (b) | $-\frac{1}{3}$ | + $\frac{1}{3}$ | $-\frac{2}{3}$ | $\frac{1}{2}$ | 0 | $\pm\frac{1}{2}$ | 0 |
| Leptons | Electron (e^-) | Muon (μ^-) | Tau (τ^-) | -1 | -1 | 0 | $\frac{1}{2}$ | 0 | $\pm\frac{1}{2}$ | 0 |
| | Electron Neutrino (ν_e) | Muon Neutrino (ν_μ) | Tau Neutrino (ν_τ) | 0 | -1 | -2 | $\frac{1}{2}$ | 0 | $\pm\frac{1}{2}$ | 0 |

The W^\pm bosons have a T_3 component of isospin and act as raising or lowering operators on the T_3 component of left handed fermions. The Z does not have a T_3 component, and thus does not act on isospin of fermions. The Z boson instead transfers momentum, energy, and spin on all fermions irregardless of their chirality.

2.1.2.3 Quantum Chromodynamics

Quantum Chromodynamics (QCD) is the QFT that describes the strong force which holds together atomic nuclei and other objects called hadrons. The strong force interacts via the color charge⁶ which can have values of either red, green, or blue. Particles that have a color charge cannot exist on their own, they must form colorless bound states called hadrons. Since the strong force grows with distance, if a quark is ejected out from a hadron, the stored

⁶This color does is not the visual color we are used to; merely a convenient analogous naming scheme.

energy is such that new particles with color charge will be spontaneously created from the vacuum, binding with the free quark in a process called hadronization. In a particle detector, the hadronization process cascades and creates showers of hadrons that are reconstructed as so called jets.

2.1.3 The Higgs Mechanism

The Higgs field is the mass generator of the SM and was first theorized by Peter Higgs [3], François Englert, and Robert Brout [4] in 1964. The SM itself has four massless bosons, B and \vec{W} ($W_{1,2,3}$), that do not correspond to the observed bosons. Instead, the Higgs mechanism couples to them via a complex scalar doublet.

$$\phi = \begin{pmatrix} \phi^+ \\ \phi^0 \end{pmatrix} \quad (2.1)$$

The scalar potential that gives rise to this phenomena can be written as

$$V(\phi) = \mu^2 |\phi^\dagger \phi| + \lambda (|\phi^\dagger \phi|)^2 \quad (2.2)$$

When $\mu^2 > 0$ and $\lambda > 0$ the minimum of the potential $V(\phi)$ is 0. However, when $\mu^2 < 0$, the scalar potential $V(\phi)$ takes the shape shown in figure 2.2. It follows that the Vacuum Expectation Value (VEV) of ϕ is then

$$\langle \phi \rangle = \sqrt{\frac{-\mu^2}{2\lambda}} = \frac{\nu}{\sqrt{2}} \quad (2.3)$$

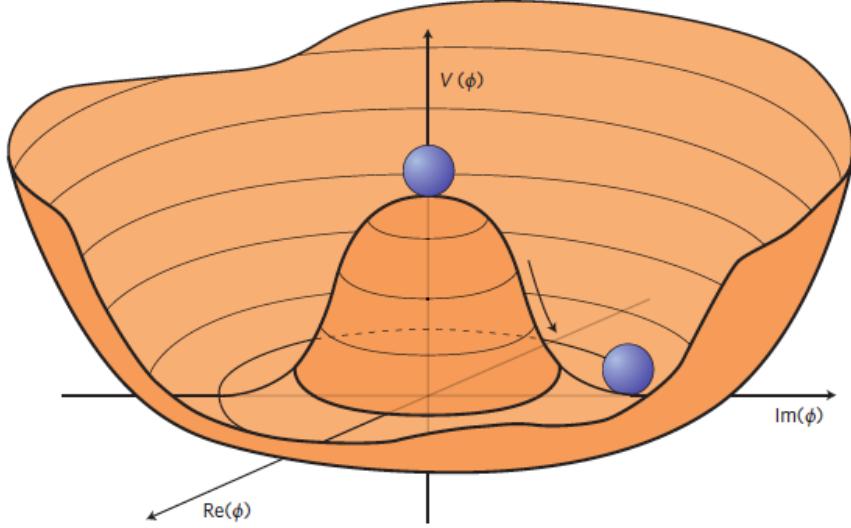

Figure 2.2: The Higgs potential defined in 2.2 with $\mu^2 < 0$ [5]

where $\nu = \sqrt{\frac{-\mu^2}{\lambda}}$. From here, convention states to choose an arbitrary direction of the fluctuation as

$$\phi^0 = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ \nu \end{pmatrix} \quad (2.4)$$

By choosing these values three of the bosons are absorbed in giving mass to the W^\pm and Z^0 bosons leaving the final as the real scalar field $h(x)$

$$\phi(x) = \phi^0 + h(x) \quad (2.5)$$

Substituting the definition of ϕ^0 yields

$$\phi = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ \nu + h(x) \end{pmatrix} \quad (2.6)$$

which couples to the SM bosons via

$$\left(\frac{1}{2} g \vec{\sigma} \cdot \vec{W} + \frac{1}{2} g' B \right) \phi^0 \quad (2.7)$$

, where $\vec{\sigma}$ are the Pauli matrices, g is the weak coupling constant, and g' is the hypercharge coupling constant. From this coupling, there are four eigenstates which correspond to the observed bosons

$$\begin{aligned} W^\pm &= \frac{1}{\sqrt{2}}(W_\mu^1 \mp iW_\mu^2) \\ Z^\mu &= \frac{-g'B_\mu + gW_\mu^3}{\sqrt{g^2 + g'^2}} \\ A^\mu &= \frac{gB_\mu + g'W_\mu^3}{\sqrt{g^2 + g'^2}} \end{aligned} \tag{2.8}$$

These eigenstates have corresponding mass values of

$$\begin{aligned} M_W^2 &= \frac{1}{4}g^2\nu^2 \\ M_Z^2 &= \frac{1}{4}(g^2 + g'^2)\nu \\ M_A^2 &= 0 \end{aligned} \tag{2.9}$$

The eigenstate labeled here as A is the photon. The Higgs boson was discovered in 2012 by the ATLAS and Compact Muon Solenoid (CMS) collaborations at CERN with a mass of 125 GeV [6]. The ATLAS result in the $H \rightarrow \gamma\gamma$ can be seen in Figure 2.3. The scalar boson that was found appears to be the SM Higgs Boson with the properties shown in Table 2.4.

Table 2.4: The Higgs boson's properties [2]

| Field Theory | Boson | Spin | EM Charge | Color | Mass | Y_W | T_3 |
|-----------------|-----------|------|-----------|-------|-----------------------|------------------|---------|
| Higgs Mechanism | Higgs (H) | 0 | 0 | X | 125.25 ± 0.17 GeV | $\pm\frac{1}{2}$ | ∓ 1 |

2.2 Supersymmetry

While the SM describes a wide range of physics to a high degree of accuracy, it is not without issues. For instance, the SM does not offer an explanation for gravity, dark matter, or the observed matter-antimatter asymmetry of the universe. In addition, the SM predicts the mass of neutrinos to be 0. Observed neutrino mixing, where $\nu_e \rightarrow \nu_\mu$, $\nu_\tau \rightarrow \nu_\mu$, etc., contradicts this; neutrinos must have mass [2].

One promising model that offers solutions to many of these issues is SUSY. As discussed previously, the SM is built upon symmetries, and the breaking of these symmetries gives us electroweak unification. SUSY proposes another symmetry, this time between fermions and bosons.

$$\begin{aligned} Q|Fermion\rangle &= |Boson\rangle, \\ Q|Boson\rangle &= |Fermion\rangle \end{aligned} \tag{2.10}$$

Equation 2.10 shows how the SUSY operator Q acts on particles. Here, Q provides a bosonic supersymmetric partner to every fermion and vice versa. SUSY naturally offers solutions to the “hierarchy problem” with the SM.

The hierarchy problem arises from the difference in electroweak ($M_W \sim 100$ GeV) and Planck ($M_P \sim 2.4 \times 10^{18}$ GeV) mass scales. For the Higgs mass to be on the scale of $M_H \sim 125$ GeV incredibly large and small mass terms must cancel perfectly, leading to a feeling of “unnaturalness”. SUSY brings many new particles into the picture, theorized to occupy the intermediate mass range leading to a more natural theory.

2.2.1 MSMM Particles

SUSY is a large group of theories that include theories with various numbers of additional superpartner particles. The MSSM is the smallest extension of the SM that introduces SUSY. In the MSSM, each SM particle is part of a supermultiplet with it's superpartner where both particles have the same quantum numbers, except spin. If this supersymmetry is unbroken, then the superpartner and the SM particle would have the same mass as well. However, SUSY has not been observed, so the supersymmetry must be broken putting the mass scale on the TeV scale. Table 2.5 lists the MSSM supermultiplets and the associated naming conventions.

2.2.2 2 Higgs Doublet Model

Having only one Higgs chiral supermultiplet with hypercharge $Y_W = \pm \frac{1}{2}$ leads to a gauge anomaly. This can be resolved by introducing two Higgs doublets with hypercharge $Y_W = \frac{1}{2}$ and $Y_W = -\frac{1}{2}$. Such is the case in the MSSM which requires two complex doublet scalar fields where one couples to the up-type quarks and the other couples to down-type quarks and charged leptons. The MSSM has 8 degrees of freedom. Following the same type of mechanism described in subsection 2.1.3 three of these degrees of freedom give the observed W^\pm and Z^0 bosons. This leaves the extended Higgs sector shown in table 2.6, where the h^0 is the SM-like Higgs that was discovered by ATLAS and CMS in 2012. When referring to the charged Higgs bosons, we often refer to them using one symbol H^\pm . In the 2HDM there are two free parameters⁷, the masses of the H^\pm and the ratio of their vacuum expectation values which is defined as $\tan \beta$. These types of models are referred to as Type II 2HDM. At

the time of writing, the extended Higgs sector is an active area of research with many new searches actively being performed [2].

2.3 Charged Higgs Bosons

Since the H^\pm couplings are proportional to the fermion masses, the main production modes at the LHC are through $t\bar{t}$ and Wt diagrams where the W is replaced by a H^\pm . The production diagrams considered in this dissertation can be seen in figure 2.4. The cross section at various $\tan \beta$ values can be seen as a function of m_{H^\pm} in figure 2.5. The cross section scales with $\tan \beta$ and at very small values the top Yukawa couplings become non-perturbative, meaning they are highly unlikely to occur. In this dissertation the decay channel considered is $H^\pm \rightarrow \tau^\pm \nu_\tau$. As can be seen in figure 2.6, the $H^\pm \rightarrow \tau^\pm \nu_\tau$ decay channel is especially relevant at low m_{H^\pm} and high $\tan \beta$. The search described in this dissertation consists of two sub-channels, $\tau + \text{jets}$ and $\tau + \ell$, where the associated top decays either hadronically or leptonically respectively.

Within the MSSM, several benchmarks are defined taking into account higher-order corrections and keeping the number of free parameters in the model low [10]. Figure 2.5 is made assuming the hMSSM model, where h^0 is taken as the observed 125 GeV Higgs and the absence of observed SUSY at the LHC is taken into account by setting the SUSY scale to $M_{SUSY} > 1$ TeV [11]. While Figure 2.6 shows the branching ratios of H^\pm for various $\tan \beta$ values in the m_h^{mod+} model where the benchmark scenario m_h^{max} ⁸ has been modified to interpret h as the observed boson [10].

⁸The m_h^{max} scenario is constructed to yield the highest possible mass for h at any given $\tan \beta$.

2.3.1 Previous Result

To add context to this dissertation, it is important to reference the results of the previous iteration of the search discussed in this dissertation. The ATLAS collaboration published a paper in 2018 covering the data taking years of 2015 and 2016 [8], whereas this dissertation covers the full Run-2 (2015-2018) dataset. Figure 2.7 shows the limits on the cross section and figure 2.8 shows the limits on $\tan \beta$ as a function of m_{H^\pm} .

The previous iteration of this analysis used boosted decision trees (BDT) binned in m_{H^\pm} , using five separate classifiers to cover the mass range of 90 – 2000 GeV. The mass bins can be seen as the blue dotted lines in Figure 2.7c. It is important to note the inclusion of the mass range 90 – 200 GeV, as [8] was the first search to include this mass region below the top quark mass of 175 GeV.

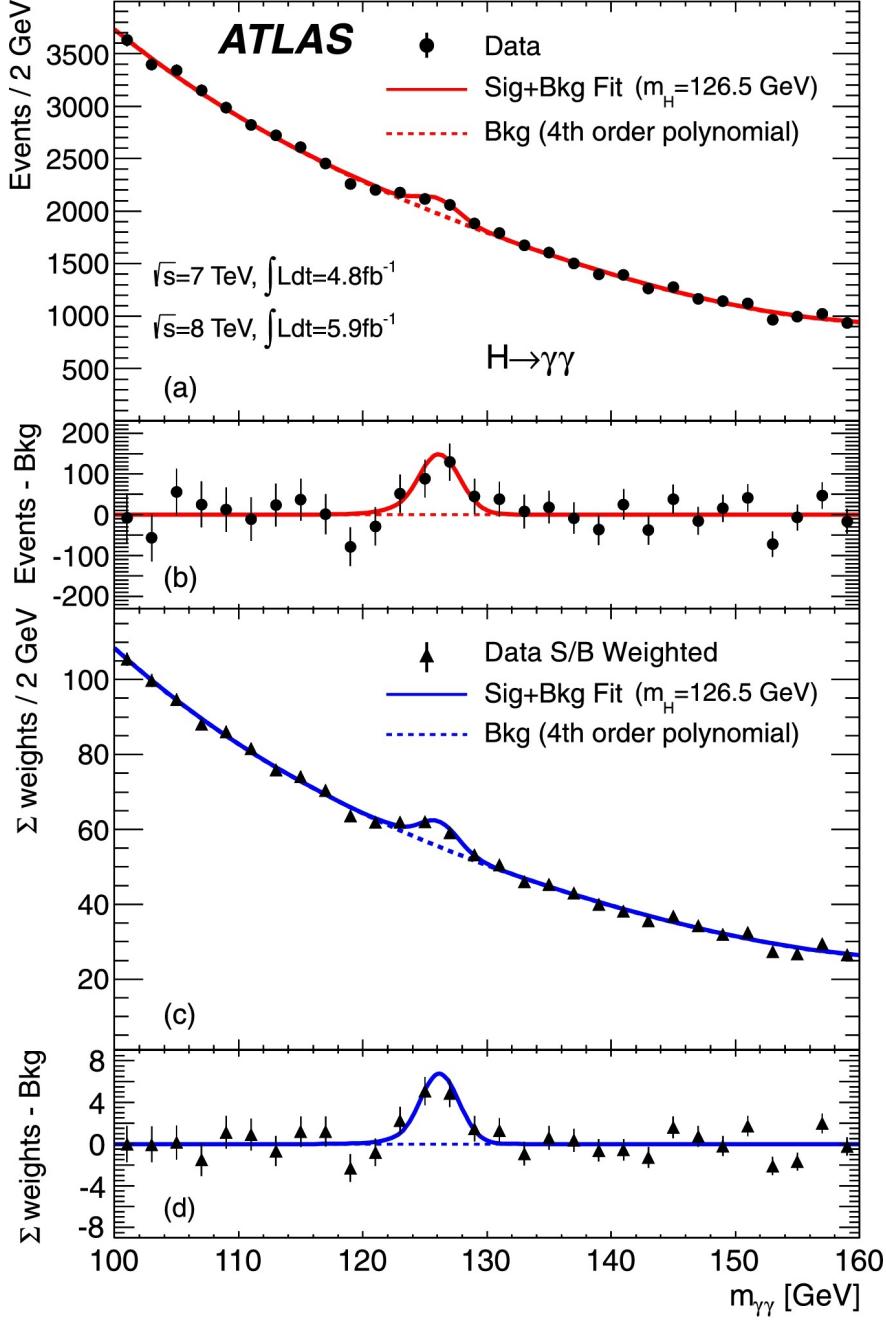

Figure 2.3: The distributions of the invariant mass of diphoton candidates after all selections for the combined 7 TeV and 8 TeV data sample. The inclusive sample is shown in (a) and a weighted version of the same sample in (c); the weights are explained in the text. The result of a fit to the data of the sum of a signal component fixed to $m_H = 126.5 \text{ GeV}$ and a background component described by a fourth-order Bernstein polynomial is superimposed. The residuals of the data and weighted data with respect to the respective fitted background component are displayed in (b) and (d). [6]

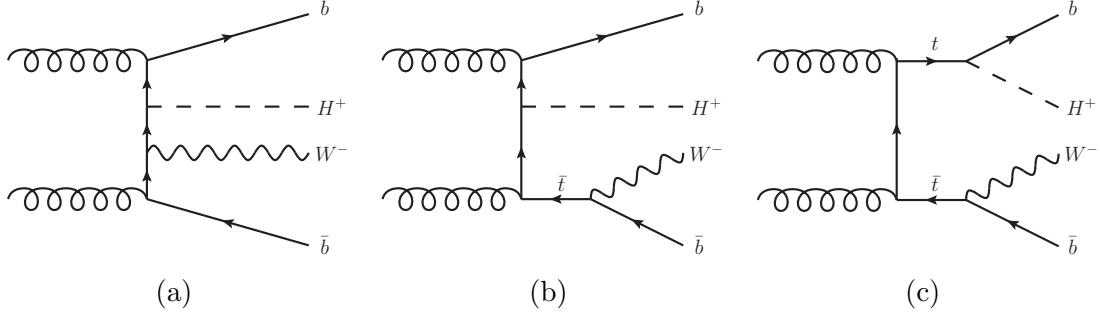

Figure 2.4: Examples of leading-order Feynman diagrams contributing to the production of charged Higgs bosons in pp collisions: (a) non-resonant top-quark production prevalent in the intermediate-mass range, (b) single-resonant top-quark production that dominates at large H^\pm masses, (c) double-resonant top-quark production that dominates at low H^\pm masses. The interference between these three diagrams becomes most relevant in the intermediate-mass region.

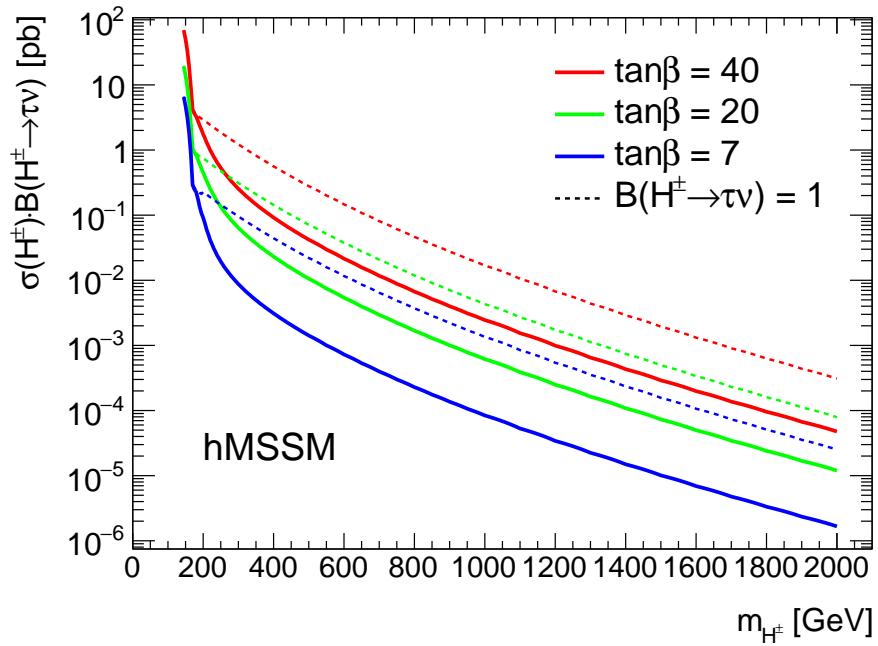

Figure 2.5: Variation of $\sigma(pp \rightarrow tbH^\pm) \times B(H^\pm \rightarrow \tau^\pm \nu_\tau)$ with the charged Higgs boson mass in pp collisions at $\sqrt{s} = 13$ TeV, for $\tan\beta$ values of 7, 20, and 40 in the hMSSM scenario. Dashed lines correspond to $B(H^\pm \rightarrow \tau^\pm \nu_\tau)$ set to 1, hence they show the dependence of $\sigma(pp \rightarrow tbH^\pm)$ with m_{H^\pm} . [8]

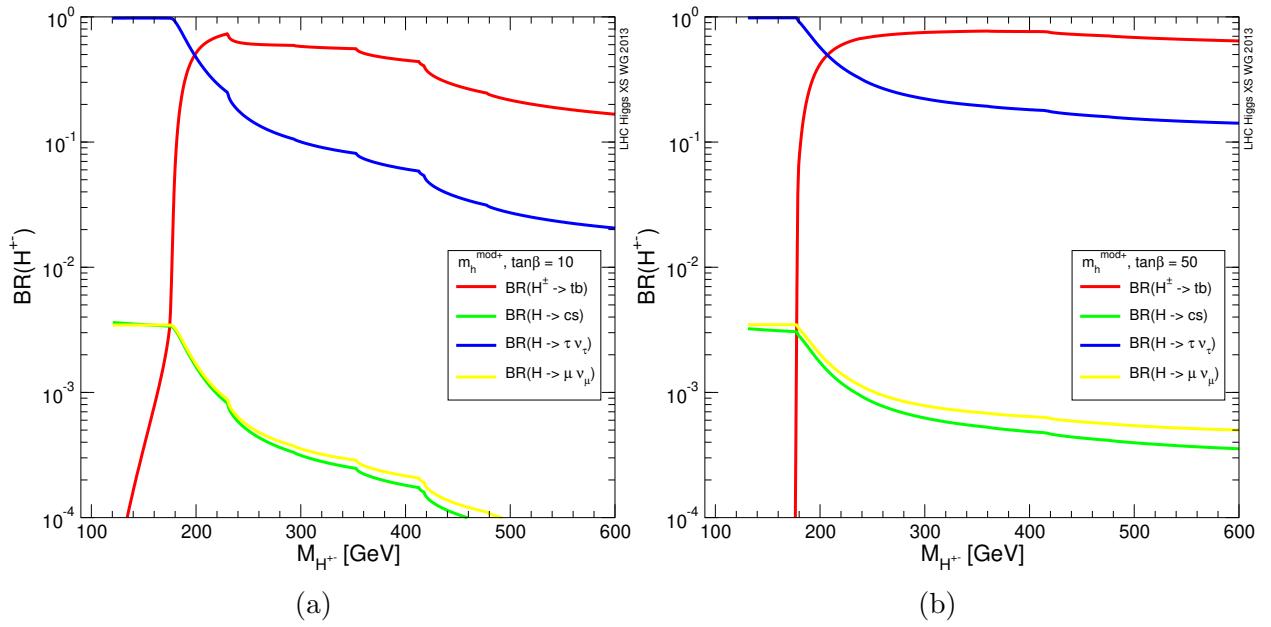

Figure 2.6: Branching fractions of H^\pm as a function of m_{H^\pm} for (a) $\tan\beta = 10$ and (b) $\tan\beta = 50$ in the m_h^{mod+} scenario of the MSSM [9].

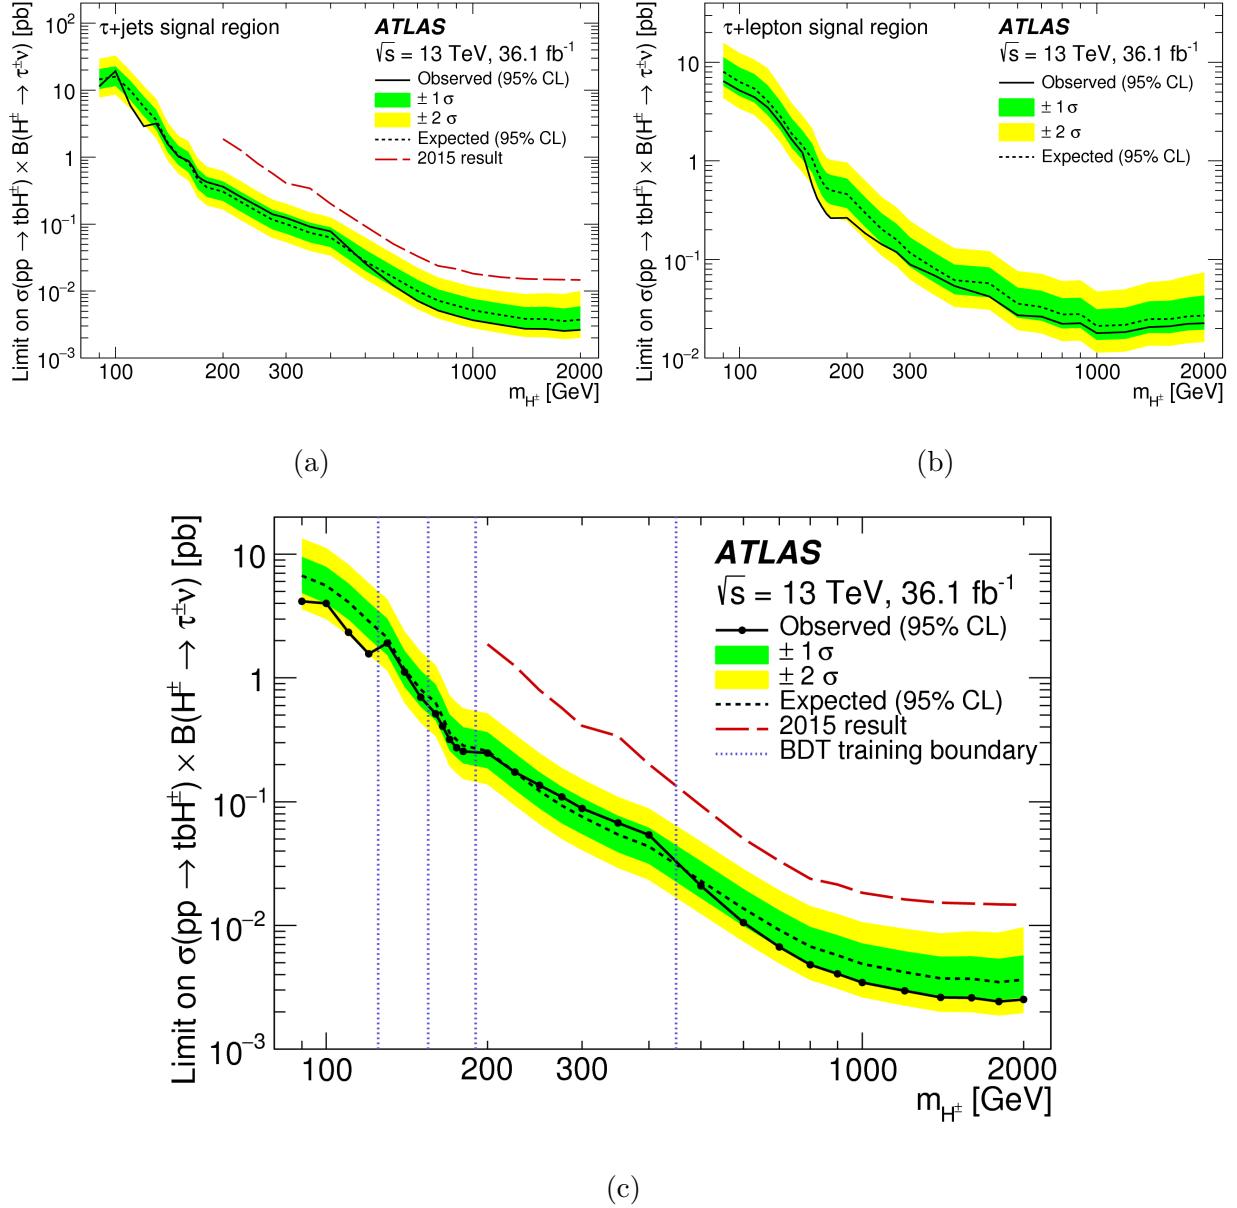

Figure 2.7: Exclusion limits at 95% CL on $\sigma(pp \rightarrow tbH^\pm \times B(H^\pm \rightarrow \tau^\pm \nu)) [pb]$. (a) is for the $\tau + \text{jets}$ subchannel (b) corresponds to the $\tau + \ell$ subchannel and (c) is the combination of the two subchannels. [8]

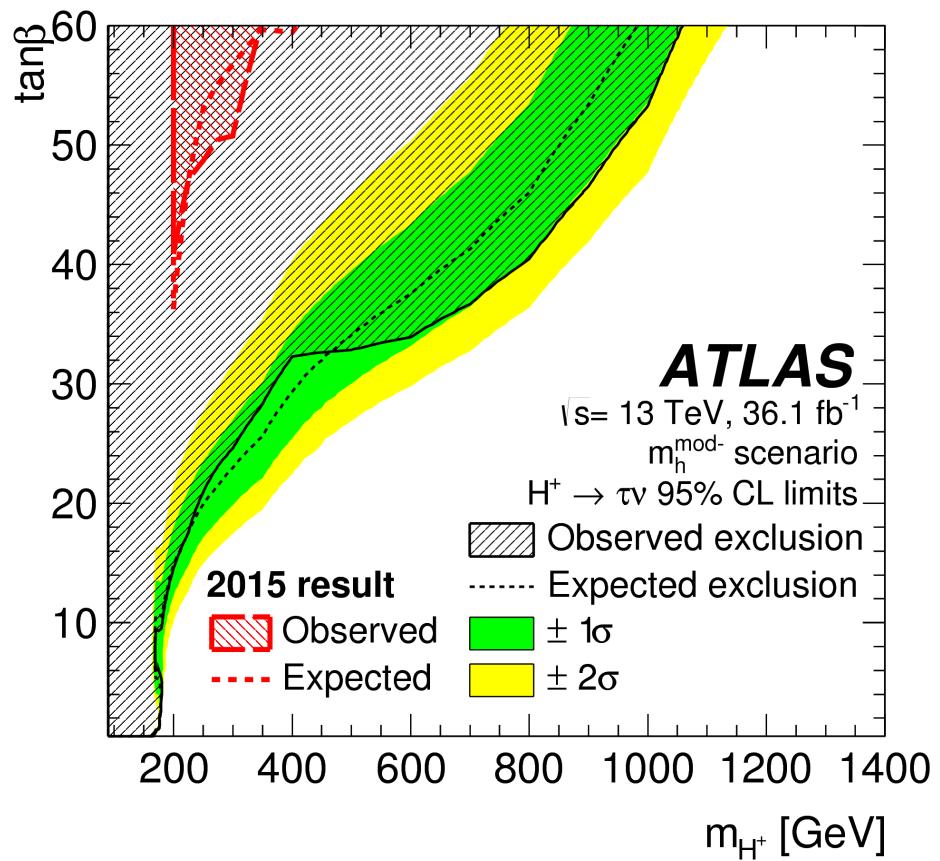

Figure 2.8: Exclusion limits at 95% CL on $\tan\beta$ as a function of m_{H^\pm} [8].

CHAPTER 3

EXPERIMENTAL APPARATUS

3.1 Particle Accelerators

To study the SM, the Higgs boson, and hints of new physics, particle accelerators are used. Particle accelerators can be categorized as either fixed target or colliders. As the naming suggests, in a fixed target accelerator the beam hits a target that then produces the desired particle collisions. A collider uses two beams, often in a circle, that are brought to collide inside a detector. The center of mass energy (E_{CM}) of a fixed target accelerator energy scales as the square root of the beam energy (E_{beam}), $E_{CM} = \sqrt{E_{beam}}$, whereas a collider scales as $E_{CM} = 2 E_{beam}$. Colliders are the preferred accelerator for maximizing the center of mass energy. The analyses discussed in this dissertation use a particle collider.

3.1.1 Hadron Colliders

Collider beams are typically made of either leptons or hadrons. Lepton colliders are often considered to be precision machines, as the longitudinal momentum is known and backgrounds are clean. The center of mass energy is well controlled in a lepton collider, meaning particles can be produced on resonance, increasing the desired particle yield. On the other hand, due to the nature of hadrons not being fundamental particles a hadron collider produces a wide variety of collisions; making hadron colliders well suited for discovery but also making for messier backgrounds. The constituents of a hadron participate in the collisions, meaning it is

impossible to know the exact longitudinal momentum of the initial state, instead momentum in the transverse plane is used (p_T). The synchrotron radiation produced from a hadron collider is typically much lower than that of a lepton collider; meaning the beams are easier to control and can be pushed to higher energies without extra loses. The center of mass energy scales with $\frac{1}{m^4}$ in a hadron collider; leading to an increased energy gain by simply using heavier particles. The analyses discussed in this dissertation use a hadron collider, the Large Hadron Collider.

3.1.2 The Large Hadron Collider

The Large Hadron Collider (LHC) is a 27 km circumference circular collider built outside of Geneva, Switzerland at Conseil Européen pour la Recherche Nucléaire (CERN). At center of mass energy 13.6 TeV (6.5 TeV in each beam), the LHC is the largest and highest energy particle accelerator ever built. There are four main collision points along the LHC: the ATLAS, CMS, ALICE, and LHCb experiments. ATLAS and CMS are general purpose particle detectors while ALICE and LHCb focus on heavy ion collisions. The numbers stated in the following sections are in reference to proton-proton collisions.

The LHC consists of 1104 NbTi superconducting dipole magnets, each being 15 m long, weighing 35 tonnes, cooled to 2 K, operating at 11,000 Amps, and produce a magnetic field of 8.3 T. A cross-section of a dipole magnet and the surrounding cryogenic system can be seen in Figure 3.1. The dipole magnets are used to bend the beam around the ring with another 128 used in the beam dump system to remove the beam safely from the LHC. A 2-in-1 configuration is used within the dipole magnets to create the required magnetic fields to bend two equally charged beams in opposite directions. A diagram of the magnetic fields in this configuration produced can be seen in Figure 3.2. To focus the beam in the horizontal

and vertical planes two quadrupole magnets are used; one magnet focuses in one plane while defocusing in the other. The end result is a horizontally and vertically focused beam. While in the LHC, the hadrons are accelerated using radiofrequency cavities. Each oppositely circulating beam is not a solid column of protons but instead consists of 2808 bunches of protons with 1.2×10^{11} protons per bunch. Collisions occur when bunches are brought to collide in a bunch crossing. Table 3.1 lists some information on the LHC.

Table 3.1: LHC parameters [12]

| | |
|------------------------------|----------------------|
| Circumference | 26,659 m |
| Dipole operating temperature | 1.9 K |
| Dipole magnets | 1232 |
| Quadrupole magnets | 392 |
| Radiofrequency cavities | 16 (8 per beam) |
| Beam energy | 6.5 TeV (13 CM TeV) |
| Protons per bunch | 1.2×10^{11} |
| Bunches per beam | 2808 |
| Revolutions per second | 11245 |
| Collisions per second | 1,000,000,000 |

3.1.3 CERN Accelerator Complex

There are a series of accelerators used to get each beam up to its final energy of 6.5 TeV. The protons used in collisions are sourced from hydrogen atoms. The hydrogen is ionized, leaving the nucleus consisting of one proton, these protons are then accelerated in radiofrequency (RF) cavities. Figure 3.3 shows in detail the full accelerator complex at CERN.¹ The protons used in the LHC start the accelerating process in the linear accelerator LINAC 2. They then are accelerated in the booster, PS, SPS, and are finally injected at the LHC where they are accelerated to the final 6.5 TeV beam energy. The final energies of

¹Figure 3.3 shows the newer LINAC 4 at the start of Run-3. This work is concerning data taken with LINAC 2.

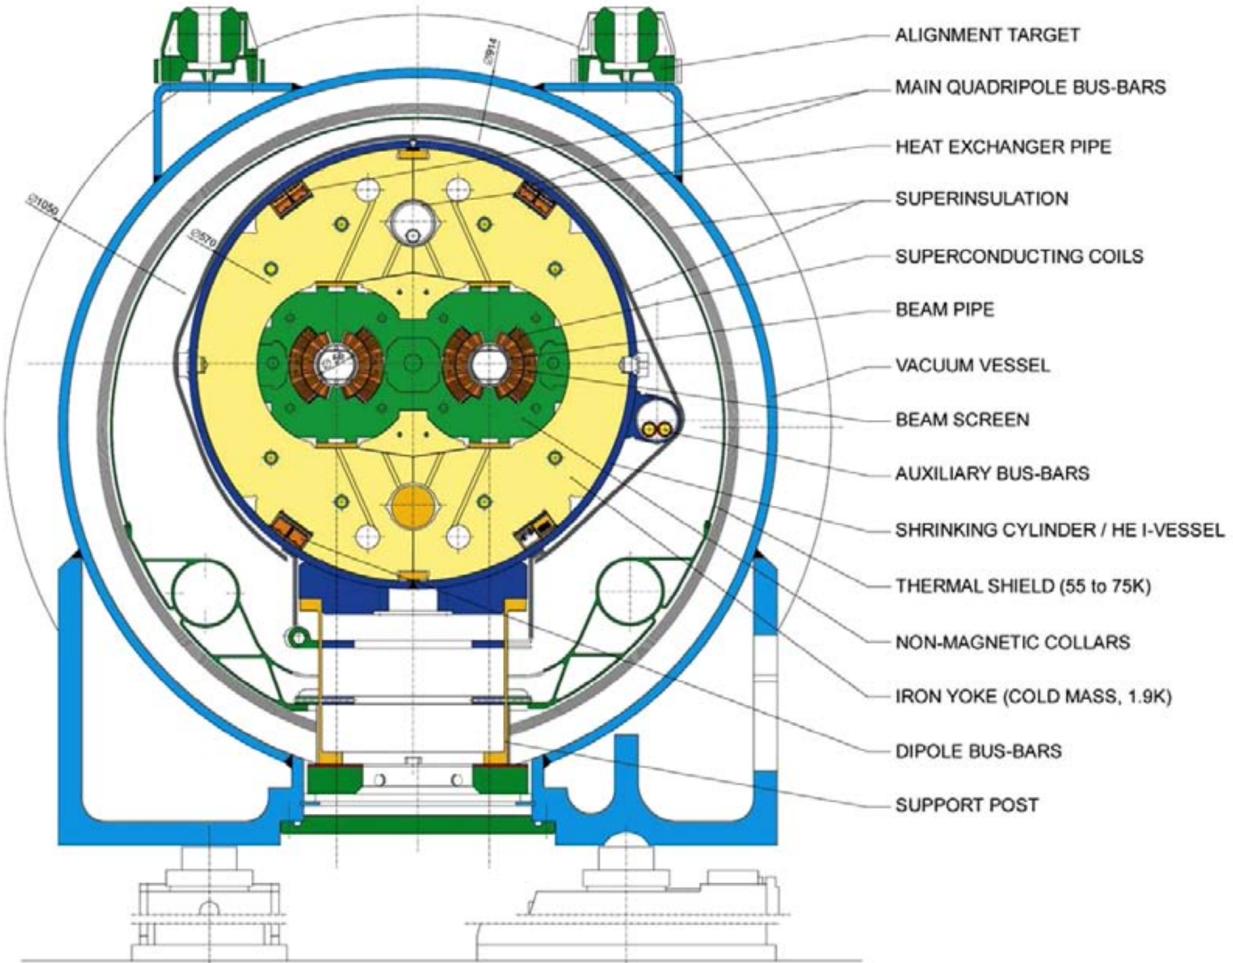

Figure 3.1: Cross-section of cryodipole (lengths in mm). [13]

protons from each accelerator can be seen in Table 3.2. Once the beams are at final collision

Table 3.2: Accelerator final energies

| Accelerator | Final Energy |
|--------------------------------|--------------|
| LINAC 2 | 50 MeV |
| Booster | 1.4 GeV |
| Proton Synchrotron (PS) | 26 GeV |
| Super Proton Synchrotron (SPS) | 450 GeV |
| Large Hadron Collider (LHC) | 6.5 TeV |

energy they are then focused, aligned, and squeezed using the series of magnets discussed

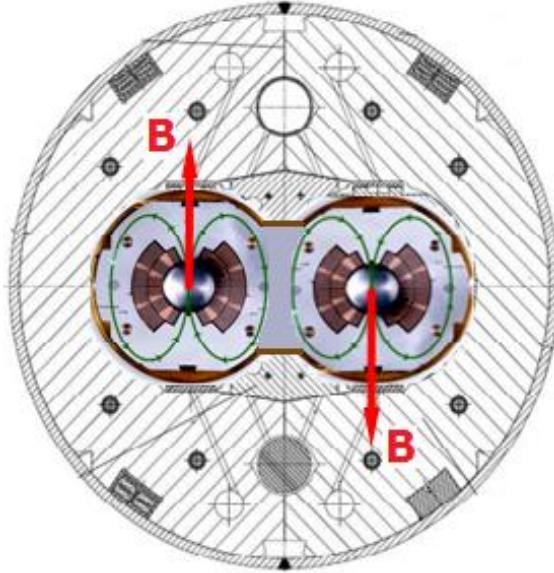

Figure 3.2: Field of the LHC dipole magnets. [14]

above. The term stable beams is used to refer to the status of the beams within the LHC when they have reached optimal conditions for data taking.

3.1.4 Luminosity

The amount of data collected from colliders is often referred to in terms of luminosity. Luminosity is measured in terms of inverse barns, where $1 b = 10^{-28} m^2$. The instantaneous luminosity of one bunch crossing can be written as

$$\mathcal{L}_{bunch} = \frac{\mu f}{\sigma} \quad (3.1)$$

The CERN accelerator complex Complexe des accélérateurs du CERN

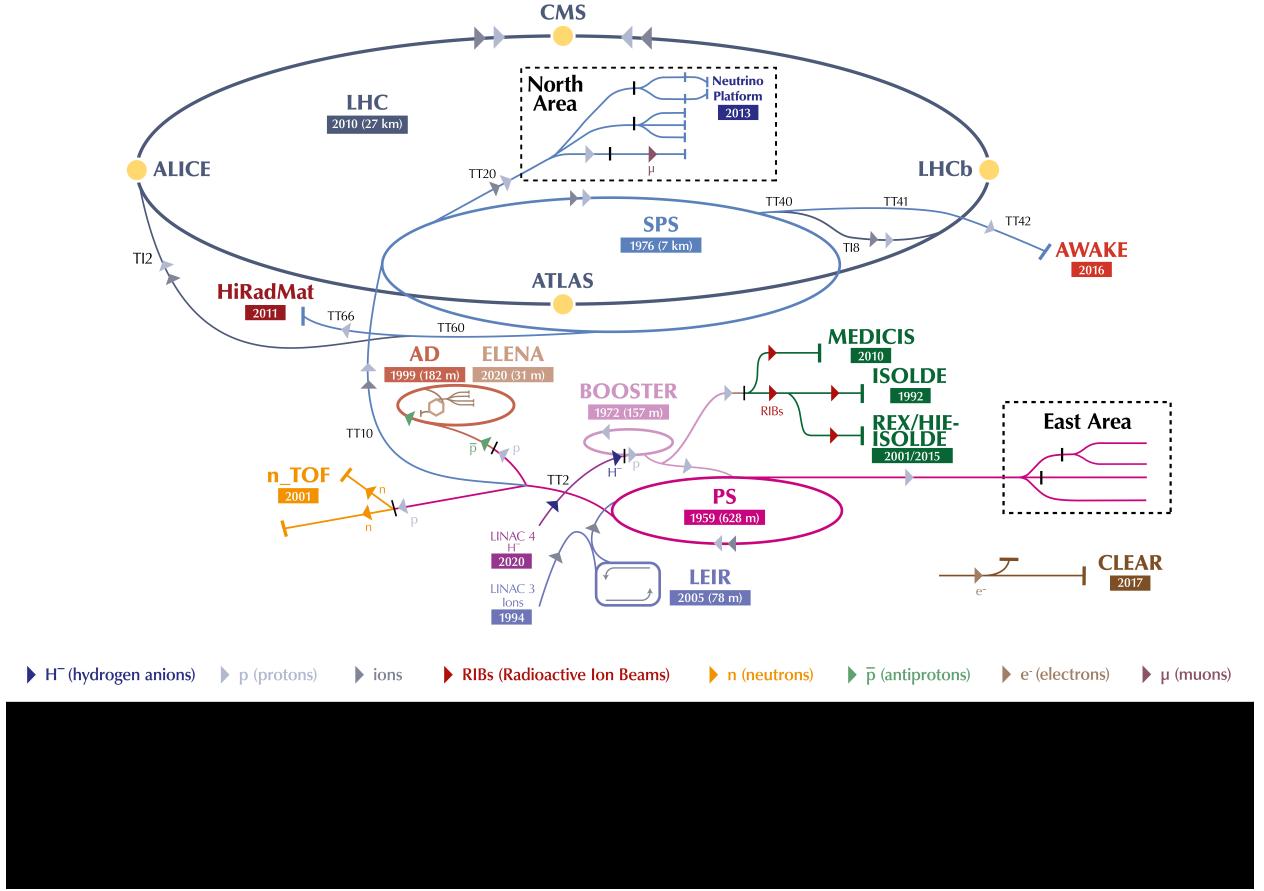

Figure 3.3: The CERN accelerator complex. [15]

where σ is the cross section and can be thought of as the probability of a collision occurring, μ is the number of inelastic interactions per bunch crossing, and f is the revolution frequency of the LHC $f = 11246$ Hz. Therefore, the total instantaneous luminosity is

$$\mathcal{L} = N_b \frac{\langle \mu \rangle f}{\sigma} \quad (3.2)$$

where $\langle \mu \rangle$ is the average number of inelastic interactions per bunch crossing.

The integrated luminosity then corresponds to the total amount of data that was taken during a time period and can be seen for the LHC Run-2 in 3.4 The value of $\langle \mu \rangle$ changed

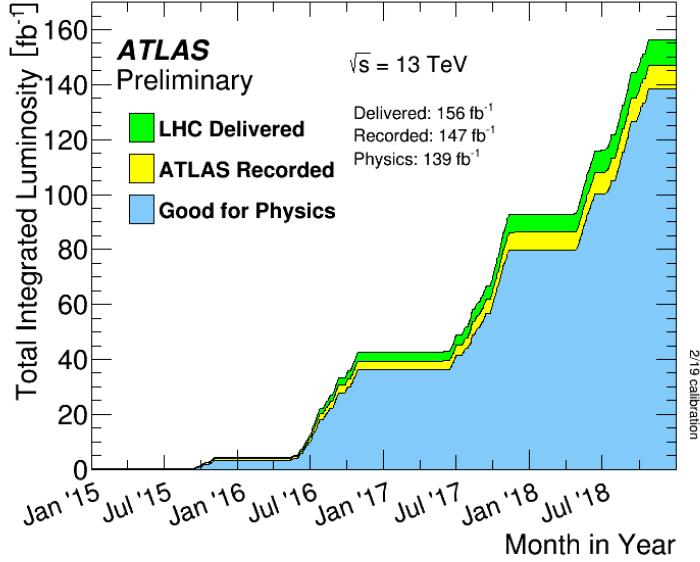

Figure 3.4: Cumulative luminosity versus time delivered to ATLAS (green), recorded by ATLAS (yellow), and certified to be good quality data (blue) during stable beams for pp collisions at 13 TeV center of mass energy in 2015-2018. The difference between the colored histograms reflects inefficiencies, especially those seen when restarting data taking [16].

throughout data taking and can be seen in Figure 3.5 and is referred to as pileup because the higher the $\langle \mu \rangle$ value, the more messy a collision becomes. The effect of high pileup can be seen in Figure 3.6, a collision event taken in 2018 with 29 reconstructed vertices shown on the bottom right as colored circles.

A common calculation using the total integrated luminosity is shown in Equation 3.3; where the number of times a particular process was produced is calculated.

$$N_x = \mathcal{L}\sigma_x \quad (3.3)$$

where again, σ is the cross section. In this case, the cross section corresponding to process x .

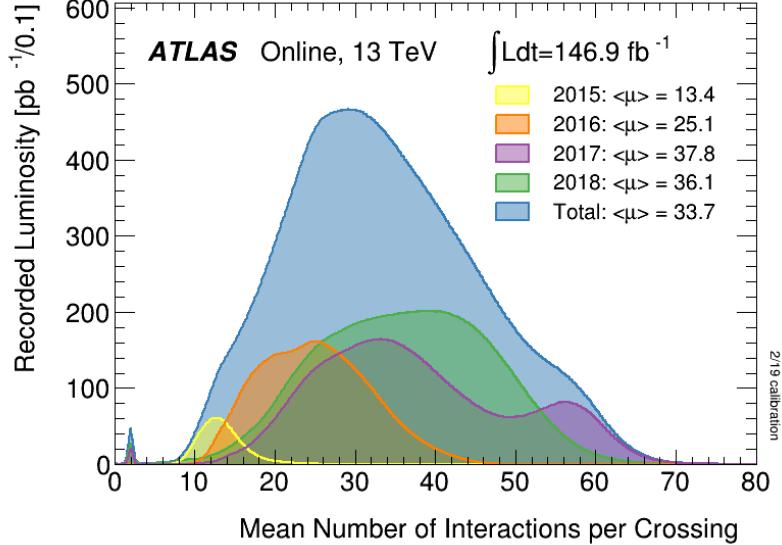

Figure 3.5: The luminosity-weighted distribution of the mean number of interactions per bunch crossing for the 2015-2018 pp collision dataset at 13 TeV center of mass energy [16].

3.2 The ATLAS Detector

The A Toroidal LHC Apparatus (ATLAS) detector is one of two general purpose particle detectors on the LHC; the other being the Compact Muon Solenoid (CMS). ATLAS is comprised of four main components: the inner detector, calorimeters, muon system, and the magnet system. Each component has several types of technology in order to measure the energy, trajectories, and determine the original particle of all possible particle decays.² The full ATLAS detector measures 44 m in length, 25 m in diameter, and weighs over 7000 tonnes. Figure 3.7 shows a 3D model of the ATLAS detector.³ All of the subdetectors output data to the TDAQ system that selects collisions with interesting physics using a complex mix of hardware and software algorithms detailed in Section 3.2.6.

²Neutrinos are not directly detected, but inferred via a missing transverse energy calculation described in Section 5.7.

³Figure 3.7 shows the New Small Wheel muon-chambers. This dissertation concerns data collected with the old Small Wheel muon-chambers.

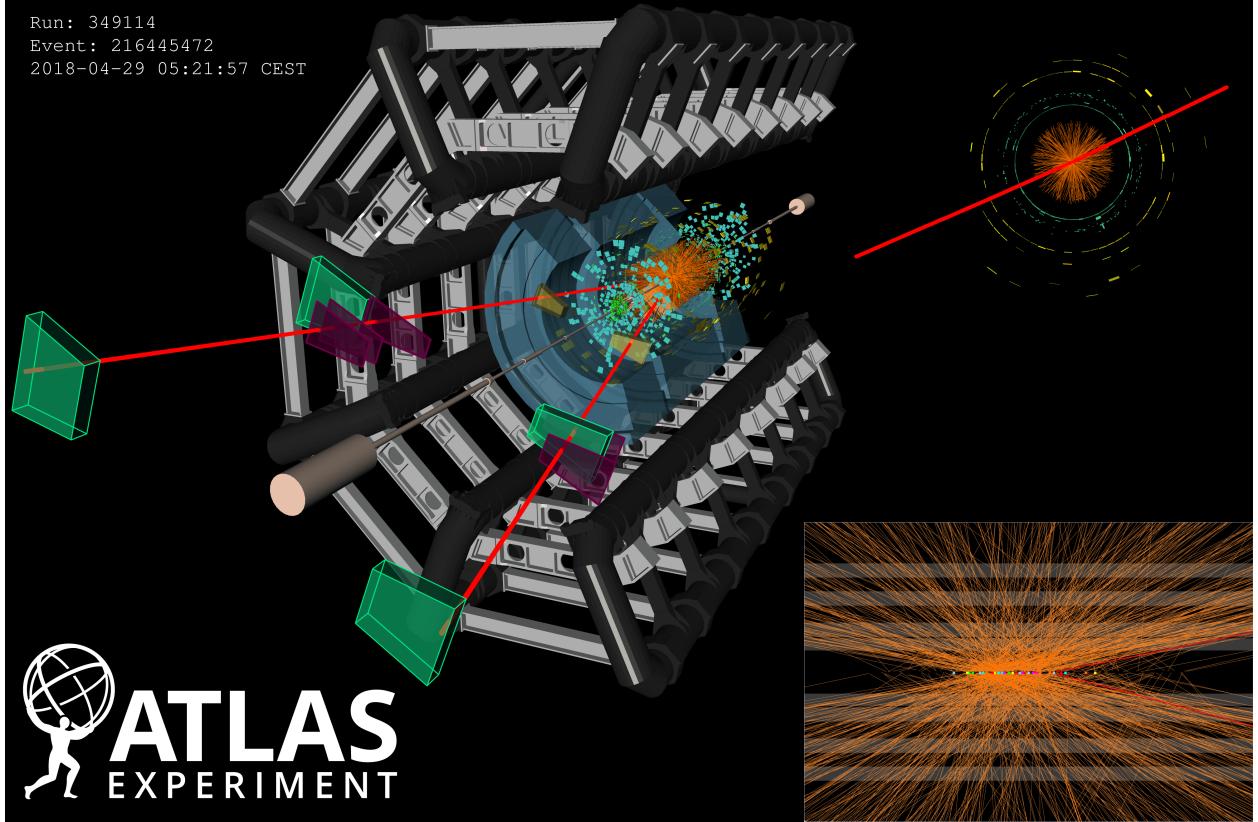

Figure 3.6: A display of a candidate Z boson event from proton-proton collisions recorded by ATLAS with LHC stable beams at a collision energy of 13 TeV. The Z boson candidate is reconstructed in a beam crossing with 28 additionally reconstructed primary vertices from the minimum bias interactions. The candidate event is reconstructed in the 2μ final state. In the left display, the red lines show the path of the two muons including the hits in the muon spectrometer and the orange tracks are the remaining charged particles from the 29 vertices, with transverse momentum above 0.5 GeV. The colored squares in the lower display correspond to the position of the reconstructed vertices. The invariant mass of the two muons is 92.3 GeV [17].

3.2.1 Detector Coordinates

Since ATLAS is a cylinder⁴, it is convenient to start with polar cylindrical coordinates. For ATLAS, the z-axis is in line with the beam line, the x-axis points towards the center of the LHC ring, and the y-axis points vertically. However, since particle collisions are relativistic

⁴The ATLAS detector is not a perfect cylinder but can be closely approximated as one.

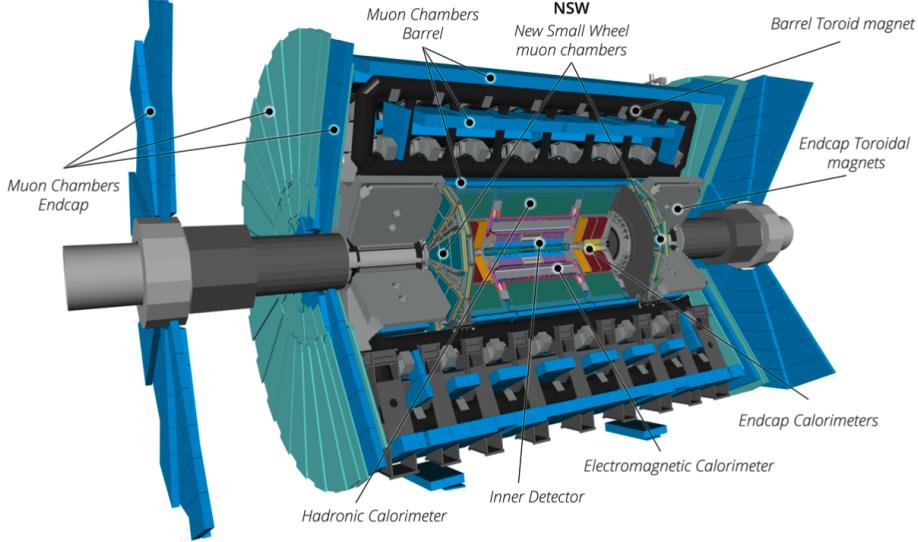

Figure 3.7: Cut-away view of the ATLAS detector with major subdetectors highlighted.
REFERENCE WAITING FOR PAPER TO BECOME PUBLIC

by nature, a set of Lorentz invariant coordinates is much more useful. The radial coordinate r defines the radial distance from the IP at the center of ATLAS, ϕ is the azimuthal angle describing the angle from the x axis and η , the pseudorapidity, is defined as

$$\eta \equiv -\ln(\tan(\frac{\theta}{2})) \quad (3.4)$$

where θ is the angle from the y -axis. The differences in η between particles is Lorentz invariant in the coordinate system of (r, ϕ, η) . Due to the large collision energies of the LHC, the pseudorapidity is a close estimate to the true rapidity (y)⁵ of the particles.

$$y \equiv \frac{1}{2} \ln\left(\frac{E + p_Z}{E - p_Z}\right) \approx \eta \quad (3.5)$$

⁵In this sense, y is now the rapidity, not the y -axis coordinate.

ΔR is used to define the distance between two particles.

$$\Delta R \equiv \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} \quad (3.6)$$

Figure 3.8 shows visually how η relates to θ . In the ATLAS detector, the central barrel section generally corresponds to a range of $|\eta| < 1$.⁶

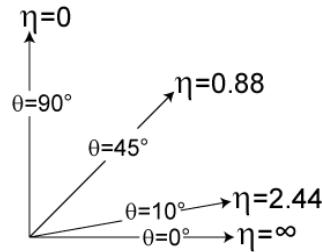

Figure 3.8: A diagram showing the pseudorapidity η and corresponding θ values. [18]

3.2.2 Magnet Systems

The ATLAS detector makes use of two superconducting magnet systems; a central solenoid and a toroid system. Both systems provide large magnetic fields to curve charged particles. The curvature can be used to measure the electromagnetic charge and charge to mass ratio, effectively measuring the momentum of charged particles. Figure 3.9 shows the magnets in ATLAS.

3.2.2.1 Solenoid System

The central solenoid encases the Inner Detector (ID), creating an axially symmetric 2 T magnetic field. This magnetic field bends charged particles in the transverse plane

⁶The exact $|\eta|$ range differs between each subdetector.

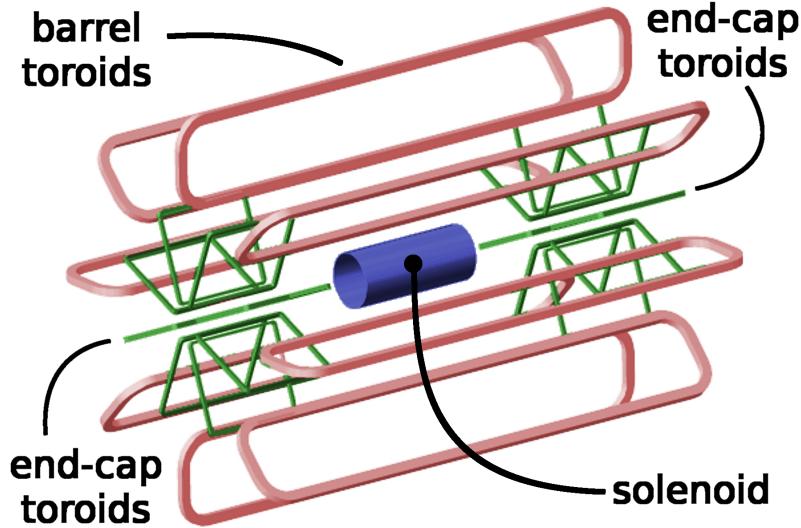

Figure 3.9: The ATLAS magnet systems. **REFERENCE WAITING FOR PAPER TO BECOME PUBLIC**

throughout the ID. The solenoid magnet itself measures 5.3 m in length and 2.63 m in diameter. In an effort to decrease the amount of material in front of the calorimeters the solenoid magnet was made to be thin. It is a single-layer coil with approximately 1200 turns of NbTi superconducting wires encased in Al-Cu to structurally stabilize the magnet material [19]. The steel structure within the Tile calorimeter acts as the magnetic flux return for the solenoid magnet system. 70% of this flux passes through the supporting girder structure, 25% through the active calorimeter material, and roughly 2% through the front-plates of the Tile calorimeter [20].

3.2.2.2 Toroid System

The ATLAS detector gets its name from the toroidal magnetic system that is critical in the measurements of muon properties. The toroid system bends any charged particles that make it past the calorimeters along the beam axis. This is achieved through a radially

symmetric magnetic field of 3.9 T in the barrel and 4.1 in the end-caps. The barrel toroid system is comprised of 8 air core superconducting toroid magnets that each measure 25 m in length, 10 m in diameter, and weigh 750 tonnes. The superconducting wires are the same used in the solenoid, NbTi encased in Al-Cu [21]. Each magnet is encased in a stainless steel cryogenic chamber, or cryostat. The toroid magnet system has two end-cap toroids that are very similar in construction to the barrel toroids. The end-cap toroids also have 8 coils measuring 5 m in length and 10 m in diameter. Instead of individual cryostats for each coil, the end-caps are encased in large cryostats that hold all 8 coils. This allows the end-caps to be pulled out and offers easy access to the rest of the detector. Just like with the central solenoid system, the design of the toroid system was chosen to limit the amount of material between detector components. A solenoid magnet of similar size to the toroid system would not only add more material, but would be cost prohibitive as well.

3.2.3 Inner Detector

The ID is the inner-most detector, closest to the IP and is used to track the trajectory of charged particles leading to the measurement of electromagnetic charge and momentum. The ID is immersed in the 2 T magnetic field provided by the central solenoid described in section 3.2.2.1 and covers a pseudorapidity range of $|\eta| < 2.5$. The three subdetectors within the ID can be seen in Figure 3.10, the Pixel, Semiconductor Tracker (SCT), and the Transition Radiation Tracker (TRT). Like the toroid system, and many of the other subdetectors, the ID is comprised of barrel and end-cap segments. The ID barrel section is 1.6 m in length and covers $|\eta| < 1$ while the end-caps measure over 7 m in length and cover $1 < |\eta| < 2.5$.

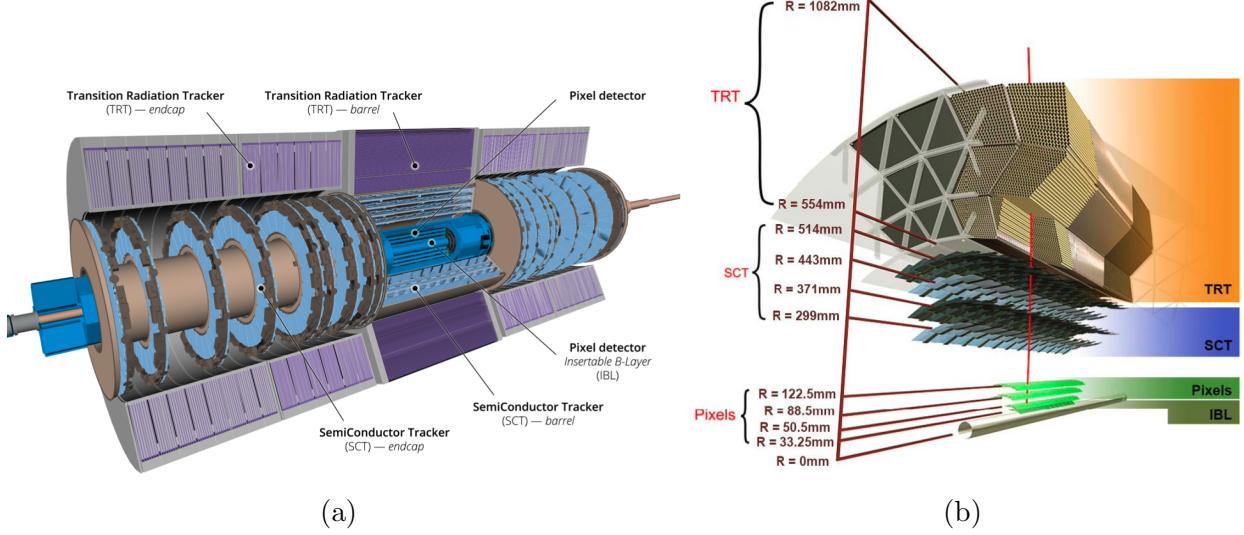

Figure 3.10: (a) Cut-away view of the ATLAS Inner Detector. (b) Cross-sectional view of the ATLAS Inner Detector. **REFERENCE WAITING FOR PAPER TO BECOME PUBLIC**

A track is considered good if there are hits in at least 3 pixel layers and 8 strips. The ID tracking system was designed with a resolution of

$$\frac{\sigma_{p_T}}{p_T} = 0.05\% p_T \oplus 1\% \quad (3.7)$$

3.2.3.1 Pixel

The detector closest to the beam and IP is the Pixel Detector. The Pixel Detector is designed to measure particle hits with high-precision and high-granularity. The barrel Pixel detector consists of three layers of n-type silicon substrate with n-type implants. The closest layer to the IP sits at 50.5 mm and the outermost layer extends out to 12 cm. This combination gives the Pixel Detector the ability to determine the impact parameters of collisions with incredible precision. Due to the high radiation dose this close to the IP, the Pixel Detector was designed to be operated only in partial depletion. Each pixel cell measures $200\mu m \times 400\mu m \times 250\mu m$. There are five Pixel disks on each end-cap of the ID. In total

there are 1,744 modules, with 46,080 readout channels per module, giving over 80 million channels with a spatial resolution of $10\ \mu m(R - \phi) \times 115\ \mu m(z)$ [22].

In order to keep up with the increased demand of Run-2 data taking conditions, an additional layer of pixels was installed in the Long Shutdown 1 (LS1) between 2013 and 2015. This Insertable B Layer (IBL) provides even finer granularity tracking with pixel cells measuring $50\ \mu m \times 250\ \mu m$ installed at a radial distance of $R = 33.25\ mm$ from the IP and a spatial resolution of $8\ \mu m(R - \phi) \times 40\ \mu m(z)$ [23]. The IBL has proved incredibly useful in the reconstruction of displaced vertices from processes like b -jet hadronization and $\gamma \rightarrow e^+e^-$.

3.2.3.2 Semiconductor Tracker

Moving radially outward, the next subdetector is the SCT that provides tracking in the intermediate radial range from the IP and covers a range of $|\eta| < 2.5$. Similar to the Pixel Detector, the SCT has 4 barrel layers and 9 end-cap wheels on each side. The SCT provides four measurements per track via silicon microstrip detectors. Each microstrip is made of two $6.36 \times 6.40\ cm^2$ detectors glued end to end so each microstrip is $12.8\ cm$ long. Two microstrips are then glued back to back with a $40\ \mu rad$ angle. In total there are 768 strips, giving 6.2 million readout channels. The SCT has a spatial resolution of $17\ \mu m(R - \phi) \times 580\ \mu m(z)$ and can distinguish tracks with as small as a $200\ \mu m$ separation [24].

3.2.3.3 Transition Radiation Tracker

The final subdetector of the ID is the TRT ($R = 554\ mm - 1082\ mm$) . Instead of silicon detectors the TRT uses 4 mm diameter straw tubes; a hollow tube with a sense wire that is held at high voltage in the middle. The maximum length of a straw is 150 cm. The straws

are filled with a gaseous mixture of 70% Xe, 27% CO₂, 3% O₂.⁷ Charged particles ionize the gas mixture, thereby releasing an electron and an ion. The ion drifts to the straw surface and the electron drifts to the wire; this charge drift is then measured as a signal. The TRT checks the signals against two thresholds, a lower threshold for measuring the drift time to derive a position and a higher threshold that is used to identify transition radiation X-rays. Transition radiation occurs when a charged particle hits the boundary of two media with differing dielectric constants; in the case of the TRT the two media are the gas and the straw tube. The higher threshold provides discriminating power between charged pions and electrons.

The TRT consists of a barrel section and 18 wheels in each end-cap. In the barrel, there are 50,000 straws divided in two at the center to allow for two separate readouts. The end-caps have 320,000 straws. In total, there are 420,000 readout channels. Each straw provides a spatial resolution of 170 μm . [24]

3.2.4 Calorimeters

The ATLAS detector makes use of two types of sampling calorimeters, one that uses liquid argon as the active medium and another that uses scintillating plastic tiles. Both types of calorimeters are designed to fully absorb particles via showering. Incoming particles interact with an absorber material and generate secondary particles. Those secondary particles interact with the absorber and create another set of particles. This cascading effect creates showers of particles inside the calorimeters. The shape and depth of these particles is important in the design choices for the calorimeters as well as particle identification. Two helpful variables when talking about shower depth are radiation length χ_0 and nuclear interaction length λ .

⁷During Run-2 the Xe was replaced with Ar as a cost saving measure. Ar provides similar performance as Xe in tracking, but is less efficient in absorbing X-rays from transition radiation.

χ_0 is defined as the distance where a particle has lost energy via bremsstrahlung equal to $\frac{1}{e}^8$, whereas λ is the mean free path of a hadron before undergoing a inelastic nuclear interaction. In order to fully absorb a wide energy range of incident particles the calorimeters are designed such that any path through them is at least $25 \chi_0$ or 10λ . Figure 3.11 shows the calorimeter layers and their nuclear interaction lengths as a function of η .

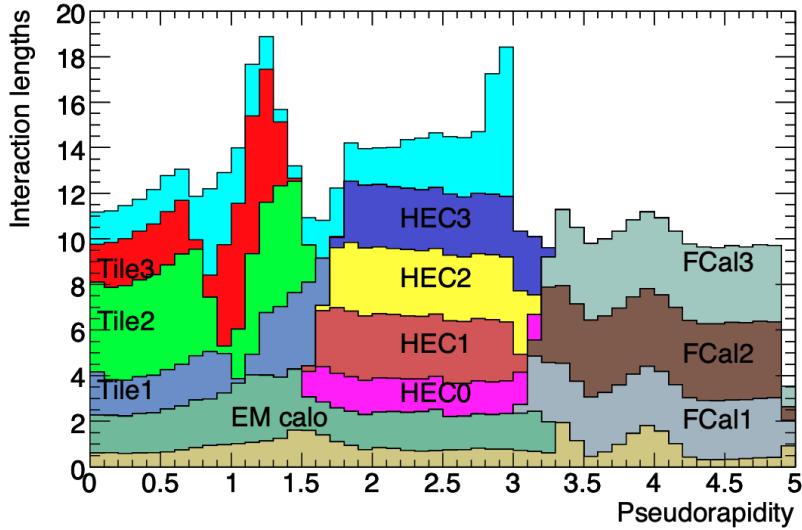

Figure 3.11: Interaction lengths as a function of η in the ATLAS calorimeters. The unlabeled brown color is the material in front of the EM calorimeters and the unlabeled cyan is the amount of material in front of the first active layer of the muon spectrometer. [25]

The design resolution of the calorimeters can be seen in Table 3.3.

Table 3.3: Design resolution of EM and hadronic calorimeters in the ATLAS Detector.

| Calorimeter | Pseudorapidity range | Resolution |
|-----------------|----------------------|--|
| Electromagnetic | $ \eta < 3.2$ | $\frac{\sigma}{E} = \frac{10\%}{\sqrt{E}} \oplus 0.7\%$ |
| Hadronic | $3.1 < \eta < 4.9$ | $\frac{\sigma}{E} = \frac{50\%}{\sqrt{E}} \oplus 3\%$ $\frac{\sigma}{E} = \frac{100\%}{\sqrt{E}} \oplus 10\%$ |

The layout of calorimeters in the ATLAS detector can be seen in Figure 3.12.

⁸ χ_0 can also be defined as $\frac{7}{9}$ of the mean free path of a high energy photon.

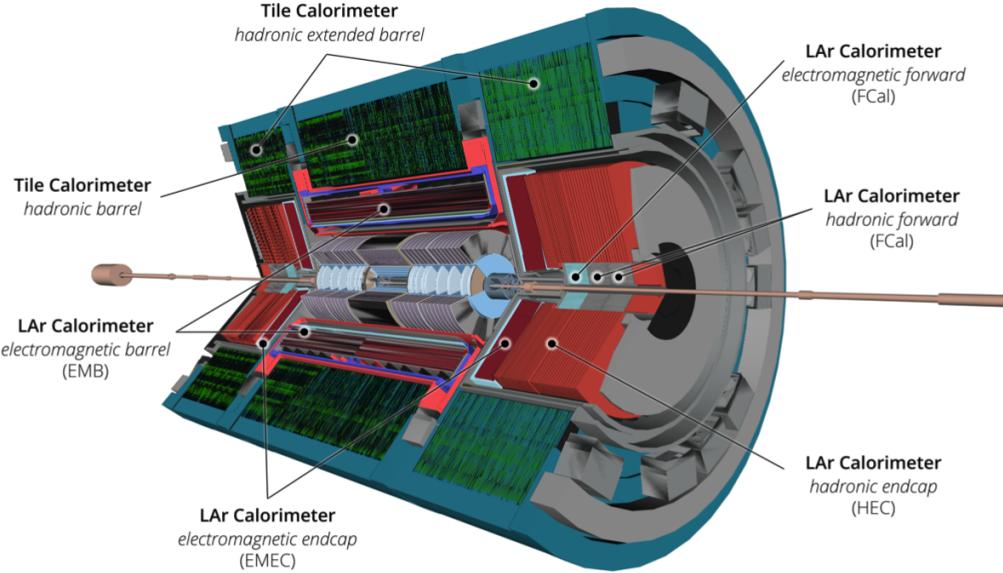

Figure 3.12: Cut-out view of the ATLAS detector’s calorimeters. **REFERENCE WAITING FOR PAPER TO BECOME PUBLIC**

3.2.4.1 Liquid Argon Calorimeters

The Liquid Argon (LAr) calorimeters are based on a similar principle to the straw tubes of the TRT described in section 3.2.3.3. In this case, the LAr is the active medium that is ionized by the incoming particle. The free electron then drifts to an electrode, copper-tungsten in the case of the barrel LAr calorimeter. The drifting electrons are then readout as an electrical signal; there are approximately 180,000 LAr readout channels in the ATLAS detector. LAr was chosen as the active medium due to its intrinsic radiation hardness, stability over time, and linear response. The LAr must be kept at very cold temperatures, around 85 K. To achieve this, the LAr calorimeters are kept in cryostats, the barrel calorimeter shares the cryostat and vacuum with the central solenoid.

There are four LAr calorimeters within the ATLAS detector. The EMB is designed for electromagnetic calorimetry with a lead-stainless steel absorber and covers a pseudorapidity

range of $|\eta| < 2.5$. Next in η is the LAr Electromagnetic End-Cap (EMEC) that also uses lead-stainless steel absorber and the LAr Hadronic End-Cap (HEC) which has a copper plate absorber; both EMEC and LAr Hadronic End-Cap (HEC) cover $1.5 < |\eta| < 3.2$. The final LAr calorimeter is the aptly named LAr Forward Calorimeter (FCAL) that covers $|\eta| < 4.9$ and has three modules. The first is optimized for EM calorimetry and uses a copper absorber. The other two FCAL modules are used to measure hadronic showers and use tungsten absorbers.

The EMB and EMEC both utilize an accordion geometry pictured in Figure 3.13 to ensure a full ϕ coverage. The EMB consists of four layers, the first being a LAr presampler of 1.1 cm

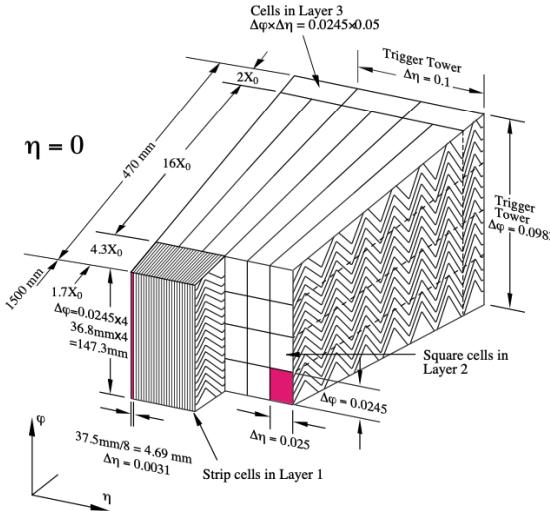

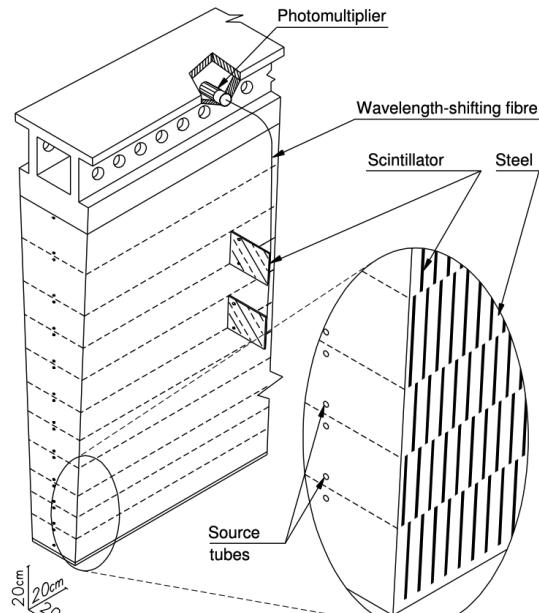

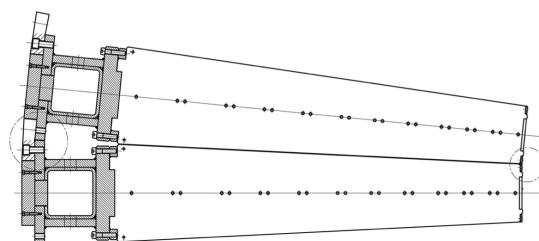

Figure 3.13: An EMB module showing the accordion geometry and granularity. **REFERENCE WAITING FOR PAPER TO BECOME PUBLIC**

thickness. The presampler is used to correct for energy losses due to material in front of the calorimeter. The first layer after the presampler is finely segmented to ensure good position measurements. The second layer is $16\chi_0$ thick and collects most of the electromagnetic showers. Typically, only the tails of EM showers make it to the third and final layer, so a courser granularity is used.

3.2.4.2 Tile Calorimeter

(a)

(b)

Figure 3.14: (a) Diagram of an individual TileCal module. (b) Azimuthal view of two TileCal modules with the IP being to the right. **REFERENCE WAITING FOR PAPER TO BECOME PUBLIC**

The hadronic TileCal is a sampling calorimeter that is designed to fully absorb hadronic showers covering a range of $|\eta| < 1.7$ at a radial distance of $2.28 \text{ m} \leq R \leq 4.25 \text{ m}$ from the IP. This radial distance translates to approximately 7.4λ . A similar design of absorber and electrode is used in TileCal to capture the full energy of hadronic showers. TileCal uses

a steel absorber. However, instead of a liquid or gas being ionized and the free electrons being collected as a signal, TileCal takes advantage of a special material called scintillating plastic. When an ionizing particle interacts with the scintillating plastic, light is created; this light is absorbed in wavelength shifting fibers. It is then re-emitted and transmitted to Photomultiplier Tubes (PMTs). The PMT signal is then shaped, amplified at two gains with a ratio of 64:1, then digitized at 40 MHz with 10-bit analogue-to-digital converters. Each cell within TileCal has 2 PMTs, giving over 10,000 readout channels. There are 256 modules within TileCal. A diagram of an individual module and the layout of two modules side-by-side can be seen in Figure 3.14.

A significant fraction of the author’s time and effort during their PhD went to data quality monitoring and maintenance of TileCal. These works are detailed in Appendix A.

3.2.5 Muon Spectrometer

High momentum muons provide a vital signature at the LHC. Muons are minimally ionizing particles, meaning they leave a small amount of energy inside detectors and travel to the edge and beyond the volume of the ATLAS detector. Instead of attempting to fully absorb muons, high precision position measurements are taken to track their trajectories. The toroid magnet system described in section 3.2.2.2 is an integral part of the Muon Spectrometer (MS); it provides the bending force, changing the trajectories to the direction of the beamline. The barrel section of the MS consists of three concentric cylindrical shells at $R = 5\text{ m}, 7.5\text{ m}, 10\text{ m}$ made of Monitored Drift Tubes (MDTs) ($|\eta| < 1$). [26] These cylindrical shells sit in-between and on the air core toroid magnets. On the 2nd and 3rd shells are Resistive Plate Chambers (RPCs) that provide quick triggering. Complimenting the barrel section are the end-caps, referred to as wheels for the MS. The wheels are placed at $|z| \approx 7.4\text{ m}, 10.8\text{ m}, 14\text{ m}$, and 21.5 m

$(2.0 < |\eta| < 2.7)$. The innermost layer of these wheels experience the highest rates of incident particles. To cope with this, Cathode Strip Chambers (CSCs) with a finer granularity than the MDTs that are used in the barrel. Similarly, Thin Gap Chambers (TGCs) are used for triggering instead of RPCs. These wheels provide spatial coordinates orthogonal to those of the precision-tracking MDTs in the barrel. Figure 3.15 shows the positioning of the various MS components.⁹

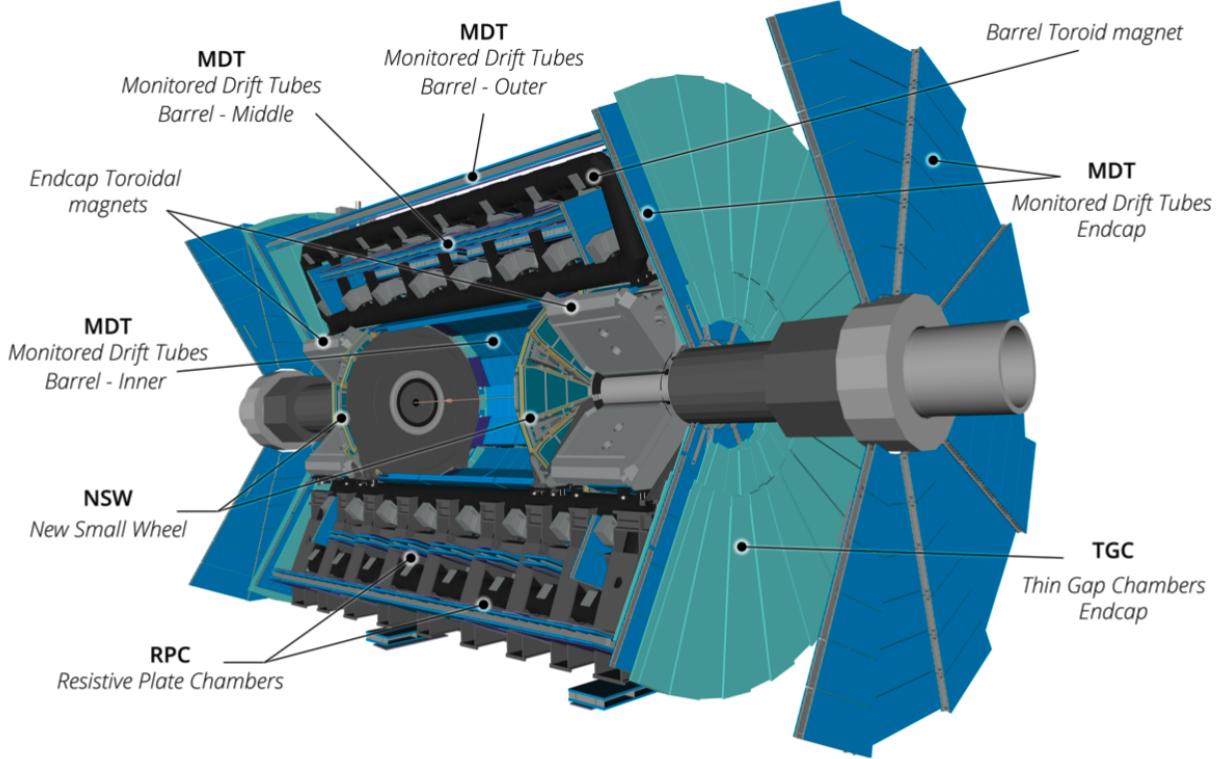

Figure 3.15: Cut-out view of the ATLAS detector Muon Spectrometer. **REFERENCE
WAITING FOR PAPER TO BECOME PUBLIC**

⁹Figure 3.15 Shows the New Small Wheel (NSW). The NSW is an upgrade to the old Small Wheels that were used in the data taking period that concerns this dissertation.

3.2.6 Trigger System

The large luminosity provided by the LHC is critical in collecting enough data to make detailed physics analyses. However, it also means that there is an incredibly large amount of data to sort through. So much that it is not possible to write out the data from every bunch crossing. As shown in Figure 3.6, even one single event can contain an inordinate amount of data. Another issue arises due to the nature of hadron collisions; in that not all bunch crossing provide hard scatter inelastic collisions that are “interesting” enough to save data on.

To solve this issue, the data coming out of ATLAS is combed through in real time at a variable rate of 1 kHz to 40 MHz. This is done with a TDAQ system. The TDAQ system used in Run-2 is described in detail here: [27]. The TDAQ system reads in data from the ATLAS detector, calculates relevant quantities, and makes a decision on if there was an event worth storing. A diagram showing the data flow into the TDAQ system is show in 3.16.¹⁰ The ATLAS TDAQ system consists of two main components, Level-1 Trigger (L1 Trigger) and High Level Trigger (HLT). The L1 Trigger is a hardware based trigger system that reads in data from the calorimeters and muon spectrometer. The L1 Trigger has a latency of $2.5\ \mu\text{s}$ and can read-out accepted events up to 100 kHz, the detector maximum readout rate. The HLT is a software based trigger system based on the offline reconstruction software. During Run-2 the HLT operated with an average output rate of 1.2 kHz, which translates to about 1.2 GB/s of data sent to permanent storage.

After the TDAQ system accepts an event, the data is set to be stored on magnetic tape for long term storage. It is also processed at the local computing farm named Tier-0 with the full reconstruction software suite described in Chapter 5.

¹⁰Figure 3.16 shows the Fast TracKer (FTK). During Run 2 FTK was undergoing commissioning and was not used in the active TDAQ system.

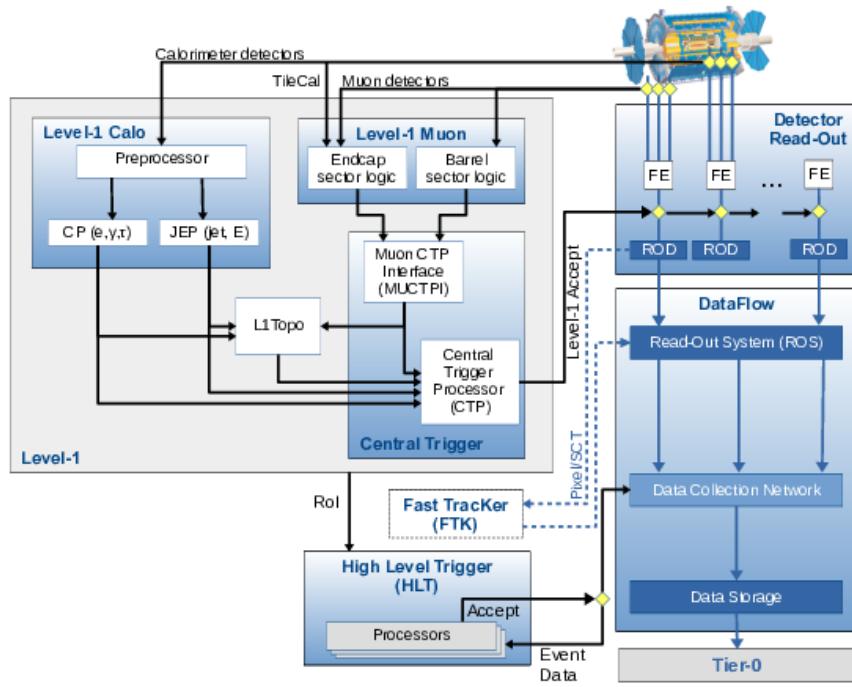

Figure 3.16: The ATLAS TDAQ system in Run-2 showing the components relevant for triggering as well as the detector read-out and data flow. **REFERENCE WAITING FOR PAPER TO BECOME PUBLIC**

CHAPTER 4

SIMULATION

The data collected by the ATLAS experiment must be compared to a control. This control is most often a dataset of simulation particle collisions that approximate to great precision physics processes and particle interaction with detector material, as well as the detector's response. Figure 4.1 shows the chain of simulations these datasets are produced by.

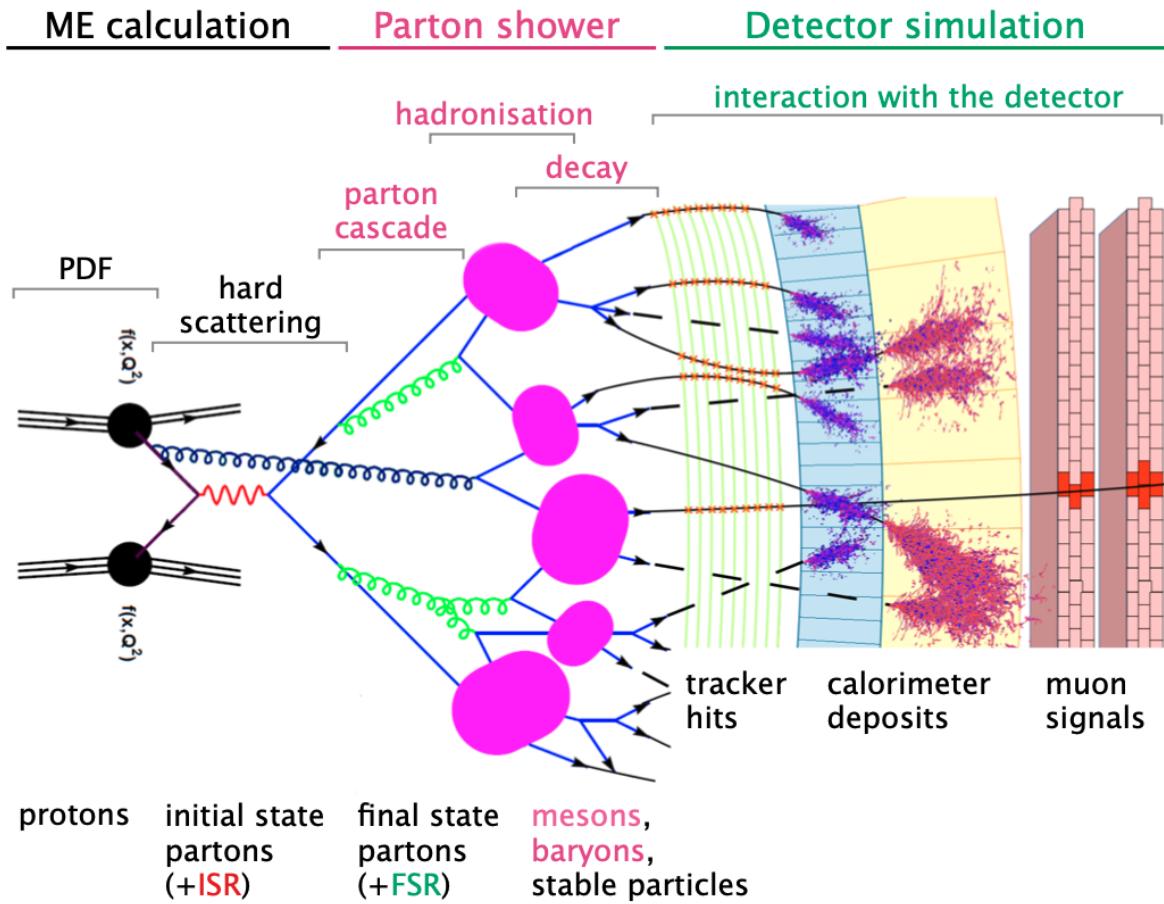

Figure 4.1: A pictorial representation of the simulation chain used in the ATLAS experiment [28].

Many particle physics experiments, ATLAS included, use Monte Carlo (MC) simulation techniques to produce these datasets. Monte Carlo simulation techniques use repeated random sampling of underlying probability density functions to closely model various processes.

4.1 Event Generation and Hadronization

Since protons and other hadrons are not fundamental particles, it is impossible to know the exact constituents (partons) that interacted during a collision. To mimic this intrinsic probabilistic nature, Parton Distribution Functions (PDFs) are used. A Parton Distribution Function (PDF) models the probability of any parton within a proton (or hadron) to carry a fraction of the beam energy at a given hadron momentum. The PDF and subsequent inelastic hard scattering of the interacting partons are modeled via a Matrix Element (ME) calculation, which can be depicted through Feynman diagrams. This ME calculation is done to fixed order in perturbation theory, Leading Order (LO), Next-to-Leading Order (NLO), Leading-Logarithmic Order (LL), etc. This first level event generation can be done by a myriad of MC event generators. Often specific choices are made based on individual generator performance for a given physics process.

The next step in the simulation chain is the parton showering and hadronization. This can be done with a different set of MC simulations. Parton showering and hadronization are complex, computationally expensive steps to simulate and are done iteratively. An example of a parton shower generator output can be seen in Figure 4.2.

The MC generators used in this dissertation are Pythia [29], Powheg-Box [30, 31], and Sherpa [32].

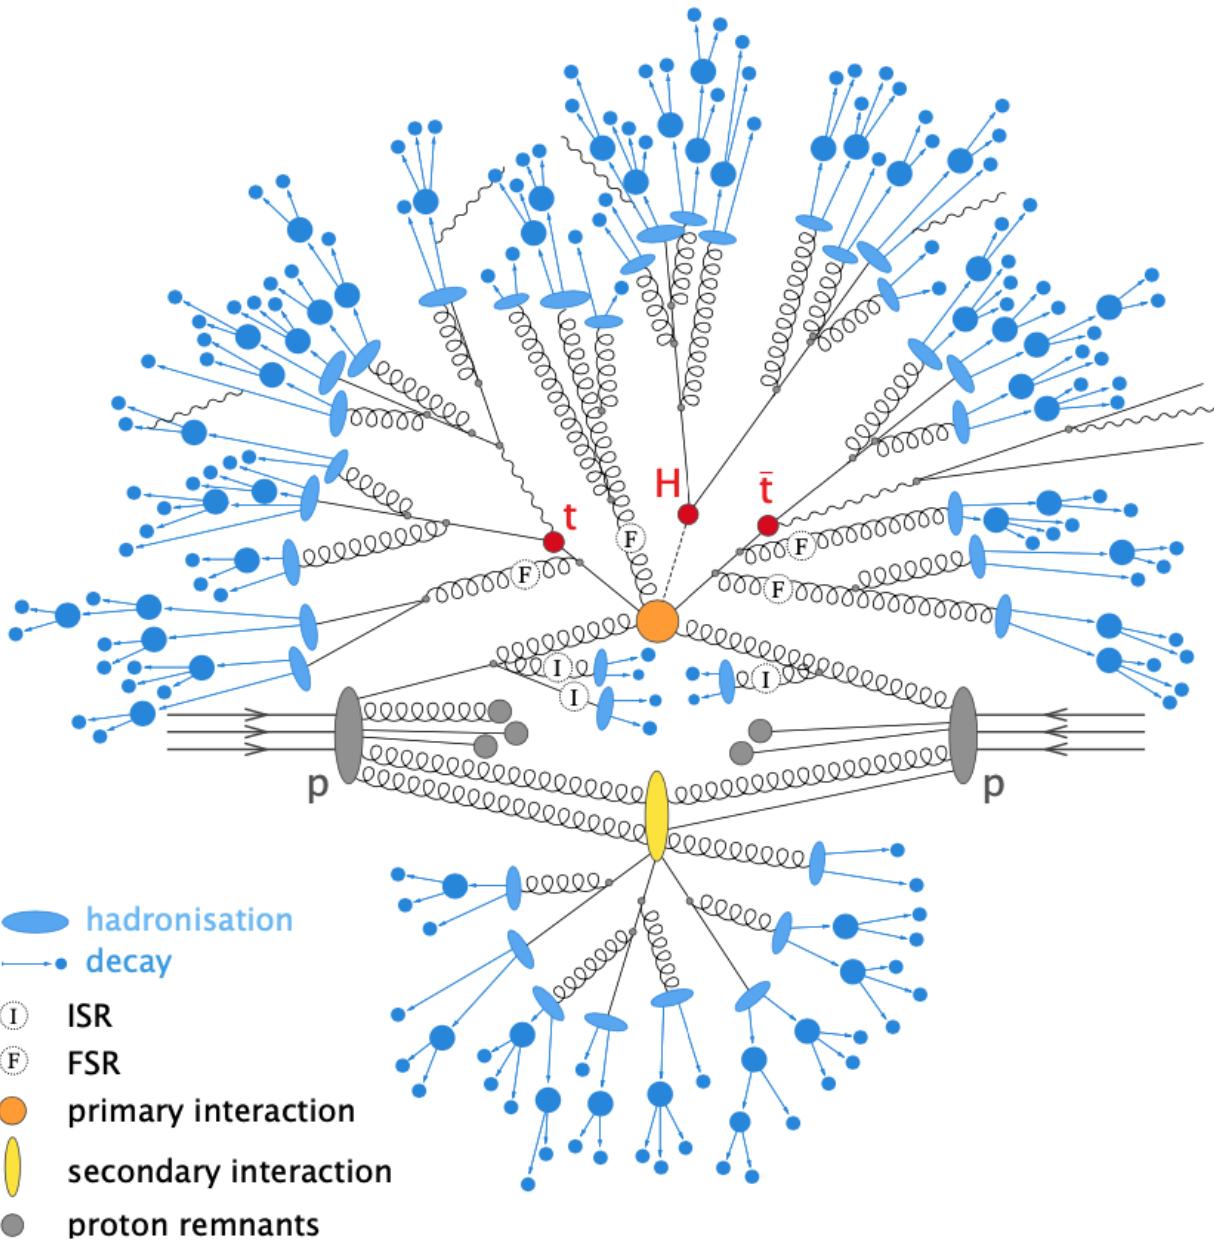

Figure 4.2: A pictorial representation of a parton shower of a $t\bar{t}H$ event [28].

4.2 Detector Simulation

The final step in the simulation chain is simulating the particle's interaction with the detector material and the detector's response. Up until this point, the MC generators used are generic non-experiment dependent simulations. The ATLAS collaboration uses a GEANT4 based generator suite to simulate these interactions [33]. These detailed simulations include all support structure, material densities, readout electronics, and digitization in order to fully simulate the path of a real particle through the ATLAS detector. In fact, these simulations are often too detailed to produce enough statistics for physics analyses. In the full simulation, around 80% of the simulation time is spent on particles traversing the calorimeters and 75% is spent on electromagnetic particles alone [34]. Instead, several methods were developed to speed up the simulation known as FAST simulations. A detailed description of the ATLAS simulation chain and options can be seen in [34]. The final simulated dataset is output into a raw data format identical to real data coming off of the ATLAS detector.

CHAPTER 5

EVENT RECONSTRUCTION

Before any physics analysis can be performed on the raw data from the ATLAS detector or MC simulations the raw datasets go through a reconstruction software suite called Athena [35]. Various algorithms are employed to identify energy deposits as particles based on shower shapes, tracker hits, calculated charge to mass ratios, etc. Figure 5.1 shows the signatures of various particles within the ATLAS detector.

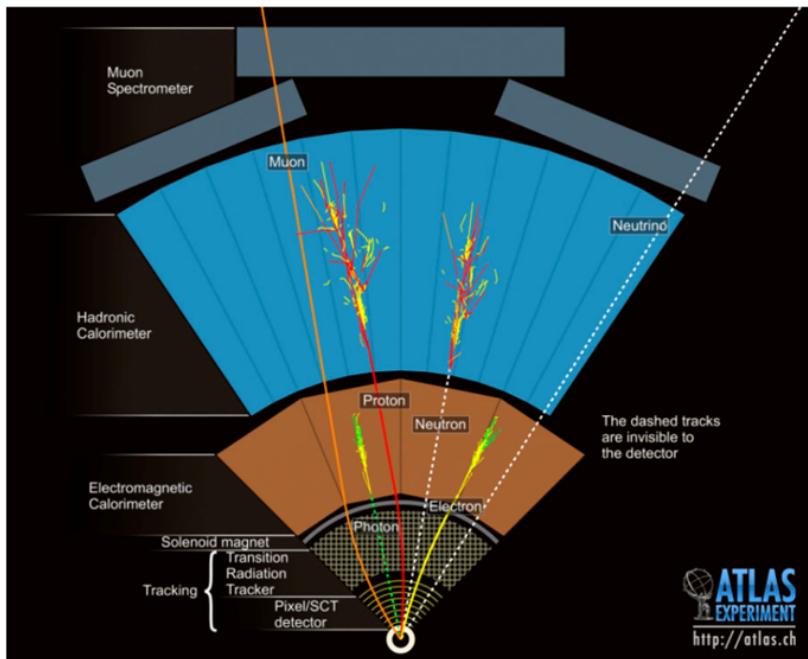

Figure 5.1: Cross section view of the ATLAS detector with subdetectors labeled. Various types of particles radial trajectories are shown [25].

The following sections detail the identification processes of muons, electrons, photons, jets, τ leptons, and a calculated quantity called missing transverse energy (E_T^{miss}). These reconstructed physics objects are the inputs to the majority of physics analyses.

5.1 Tracks

Tracks are fit-connected three-dimensional space-points in the ID. These space-points are created from clusters of hits in the ID. A set of three space-points are combined into one track seed, then fed into three methods in the ATLAS detector: inside-out, outside-in, and TRT-standalone. The inside-out method creates tracks by starting with a seed hit in the pixel detector, then SCT hits are added, finally the track is extrapolated out into the TRT. This method creates tracks of particles that are mostly produced in the hard pp interaction and has a requirement of $p_T > 400$ MeV. On the other-hand the outside-in method starts with track segments in the TRT and extrapolates towards the beamline using silicon that were not used in the inside-out method. Outside-in tracking typically reconstructs secondary vertices from particles that have long enough lifetimes to decay while inside the ID, including b quarks and τ leptons. Lastly, TRT-standalone tracks are made only from seeds within the TRT and are not extrapolated to the silicon subdetectors [36]. The reconstructed tracks are used in the identification of various types of particles.

5.2 Topological Clusters

A topocluster is defined as a cluster of topologically connected calorimeter cell signals. Topological clusters in the ATLAS detector’s calorimeters are vital to the identification of hadronic final states, meaning jets (Section 5.5), isolated hadrons, and hadronically decaying τ leptons (Section 5.6). Topoclusters are also included in the calculation of missing transverse energy discussed in Section 5.7, as they represent the direction and energy of softer particles in a collision event.

A topocluster is created via a growing volume algorithm that operates based on a set of three thresholds. These thresholds are defined using the calorimeter cell significance ξ_{cell} [37]:

$$\xi_{cell} = \frac{E_{cell}}{\sigma_{noise,cell}} \quad (5.1)$$

where E_{cell} is the energy in the calorimeter cell and $\sigma_{noise,cell}$ is the average expected noise of a given calorimeter cell. An in-depth review of how the $\sigma_{noise,cell}$ value is calculated for TileCal is given in Appendix A. A topocluster starts with a seed cell that has a significance greater than the seed threshold S . From the seed cell, all three-dimensionally neighboring cells with a significance greater than the growth threshold N are added to the topocluster. This is done repeatedly until there are no more neighboring cells that pass the requirement $|\xi_{cell}| > N$. If a neighboring cell also passes the $|\xi_{cell}| > S$ threshold, then the topocluster corresponding to the neighbor cell is merged into the original topocluster. Finally, a last layer of the topocluster is added from all neighboring cells passing a threshold of $|\xi_{cell}| > P$. In the ATLAS experiment, the threshold values are set at $(S, N, P) = (4, 2, 0)$.

5.3 Muon Identification

Muons are identified using a combination of information from the ID and the MS. Within the ID, muons leave tracks identical to any other charged particle; however, in the MS tracks are identified within the MDTs through a straight-line fit in a single layer and by doing a combinatorial search of CSC hits in the $\eta - \phi$ plane. [38] Muons are identified through five strategies, each using the information from the ID, MS, and calorimeter (in one case).

- Combined (CB): Match ID and MS tracks. Perform a combined track fit on ID and MS hits. Takes into account energy loss in calorimeters

- Inside-Out (IO): Extrapolate ID tracks, look for at least three loosely aligned MS hits. Calorimeter energy loss is accounted for.
- Muon Spectrometer Extrapolated (ME): Extrapolate MS tracks back to the beamline. No ID hits are taken into account.
- Segmented-Tagged (ST): Extrapolate ID tracks and match to MS segments with tight angular requirements. Muon parameters are taken directly from the ID.
- Calorimeter-Tagged (CT): Extrapolate ID tracks into the calorimeters. Look for energy deposits consistent with minimum ionizing particles. Tag as muon, take parameters from ID.

All muon identification strategies have a transverse momentum cut on ID tracks of $p_T^{track} > 2$ GeV, except for CT, which has a cut on the transverse momentum of the tracks of $p_T^{track} > 5$ GeV.

Reconstructed muons are divided into three Working Points (WPs) to allow analyzers a choice of purity, efficiency, and background rejection.

- Loose: Optimized for reconstruction of $H \rightarrow 4\mu$. Lowest purity and highest efficiency.
- Medium: Efficiency and purity are suitable for a wide range of analyses with small systematic uncertainties.
- Tight: High purity, slightly lower efficiency than medium WP. Significantly higher background rejection.

The analysis discussed in this dissertation uses the Loose WP for muons to allow for larger statistics in the signal region.

Talk about p_T measurement and isolation requirements

5.4 $e\gamma$ Identification

Electrons and photons deposit the majority of their energy in the EM calorimeters in similar fashion. Electrons produce Bremsstrahlung photons as they interact with the EM calorimeter, the produced photons then convert into an electron-positron pair. This process repeats and produces a shower. A photon that is produced in the ID and travels to the EM calorimeters creates a very similar shower by converting into an electron-antielectron (positron) pair. The discerning difference between an electron's signature and that of a photon is angular matching tracks. An electron carries an EM charge, thus leaving a track in the ID; whereas a photon does not carry an EM charge, therefore does not leave a track. The process of identifying an EM shower as either electron initiated or photon initiated is detailed in Ref [39]. A brief algorithm flow chart of this process can be seen in Figure 5.2. If tracks in the ID are found to match a topocluster in the EM calorimeter, then it is identified as an electron, re-clustered into so called superclusters to ensure the full shower is captured, calibrated, then lastly made into an analysis object for use in physics analyses. The same algorithm is used to identify photons with the exception of matching tracks to the ID. Instead, photons are matched to conversion vertices where the initial photon first converted into an electron-positron pair. Both electrons and photons are reconstructed at three WPs. As with muons, there are three WPs, Loose, Medium, and Tight; the stricter WPs being subsets of the looser WPs.

To ensure that an electron or photon is indeed an initial particle and not part of another shower, whether it be from a converted photon in a hadron decay, electrons from heavy flavor hadrons or a light hadron mis-identified as an electron, an isolation variable is calculated. The isolation variable is based on track isolation and defined as the sum of transverse momenta

of all tracks within a cone around the electron candidate of $\Delta R = 0.2$ or in the case of high energy photons, $10 \text{ GeV}/E_T$, where E_T is the transverse energy of the electron.

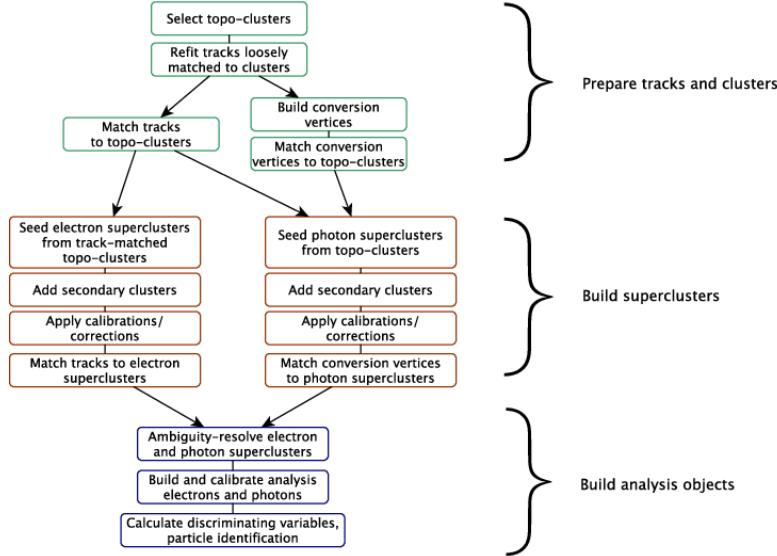

Figure 5.2: Algorithm flow diagram for the electron and photon reconstruction [39].

5.5 Jets

A jet is a reconstructed object of calorimeter energy¹ that is meant to capture the energy and direction of a hadronic shower, typically initiated from hard scatter quarks, hadrons, or gluons. There are several algorithms available to perform a clustering of calorimeter topoclusters to form jets. This dissertation uses jets created from particle flow objects. The particle flow algorithm is described in detail in Ref. [40], a flow chart of the algorithm is shown in Figure 5.3 and an idealized example of the particle flow algorithm performing the reconstruction of hadrons is shown in Figure 5.4.

¹The jet objects in this dissertation use the particle flow algorithm that includes track objects in the full jet energy calculation.

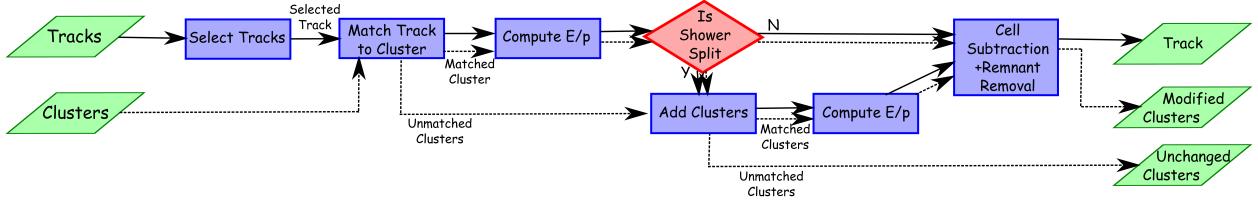

Figure 5.3: A flow chart of how the particle flow algorithm proceeds, starting with track selection and continuing until the energy associated with the selected tracks has been removed from the calorimeter. At the end, charged particles, topoclusters which have not been modified by the algorithm, and remnants of topoclusters which have had part of their energy removed remain [40].

The particle flow algorithm starts by matching selected tracks to a single topocluster. The expected energy of the initial particle in the calorimeter is calculated from the track momentum and the topocluster position. The probability of the track-topocluster system being deposited in multiple topoclusters is then calculated. The algorithm then adds in more topoclusters to the output object based on this probability. The expected energy of the initial particle is subtracted from the energy of the matched topoclusters cell by cell. If the energy of the output object is consistent with a single particle signal, then the remaining topocluster remnants are removed. The outputs of the particle flow algorithm are then fed into the anti- k_t algorithm [41] with a radius value of $R = 0.4$.

The anti- k_t algorithm is a jet finding algorithm that is collinear and infrared safe, meaning the number of identified jets does not change due to splitting or merging of high transverse momentum particles, nor the presence of soft gluon emission between jets [42]. A jet is constructed in the anti- k_t algorithm through an iterative process using a the distance parameter defined as

$$d_{ij} = \min(k_{t,i}^{-2}, k_{t,j}^{-2}) \frac{\Delta_{ij}^2}{R^2} \quad (5.2)$$

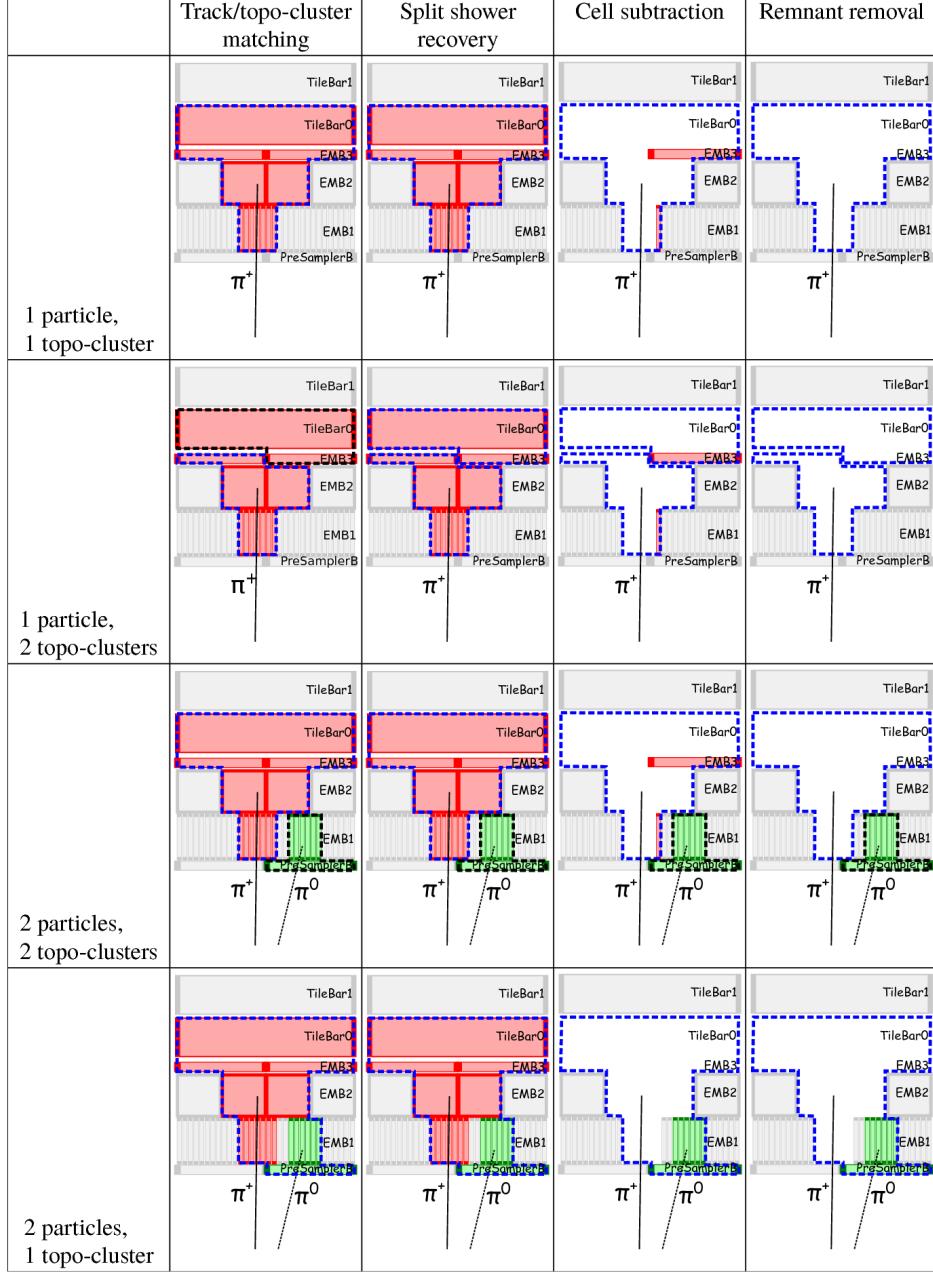

Figure 5.4: Idealized examples of how the algorithm is designed to deal with several different cases. The red cells are those which have energy from the π^+ , the green have cells energy from the photons in the π^0 decay, the dotted lines represent the original topocluster boundaries with those outlined in blue having been matched by the algorithm to the π^+ , while those in black are yet to be selected. The different layers in the EM calorimeter (Presampler, EMB1, EMB2, EMB3) are indicated. In this sketch only the first two layers of the Tile calorimeter are shown (TileBar0 and TileBar1) [40].

where k_t is the transverse momentum, R is an input parameter defining the radius of the jet cone, and Δ_{ij} is the distance between objects i and j defined as

$$\Delta_{ij} = (y_i - y_j)^2 + (\phi_i - \phi_j)^2 \quad (5.3)$$

The anti- k_t algorithm first identifies the smallest d_{ij} and clusters the particle flow objects if $d_{ij} > k_{t,i}^{-2}$. If $d_{ij} > k_{t,i}^{-2}$ then the particle flow object is discarded. This process continues iteratively until there are no more objects to consider. Objects with $\Delta > R$ are still considered, making the R input parameter an energy cut-off for clustering and not a direct radius value. Figure 5.5 shows the anti- k_t algorithm's performance compared to other jet finding algorithms. The anti- k_t algorithm results in a more conical shape than other jet finding algorithms; better encapsulating the shower profile of jets.

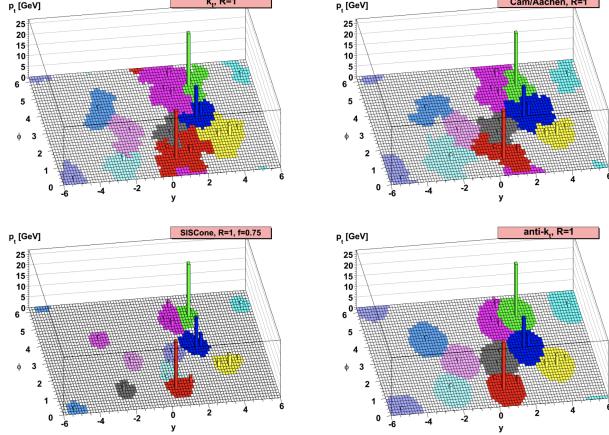

Figure 5.5: Comparison between several jet finding algorithms [41].

Talk about jet calibration

5.5.1 *b*-jet Tagging

Jets originating from hard scatter *b* quarks are an important signature in high energy physics colliders, especially so in the analysis discussed in this dissertation. An initial state *b* quark hadronizes into *B*-hadrons which have a relatively long lifetime. Due to the relativistic speeds and long lifetime of the *B*-hadrons they travel a distance away from the IP before decaying and creating a hadronic shower. This leads to a secondary vertex that can be measured. A pictorial representation is shown in Figure 5.6. The impact parameter d_0 shown is the minimum distance between the tracks from the secondary vertex and IP.

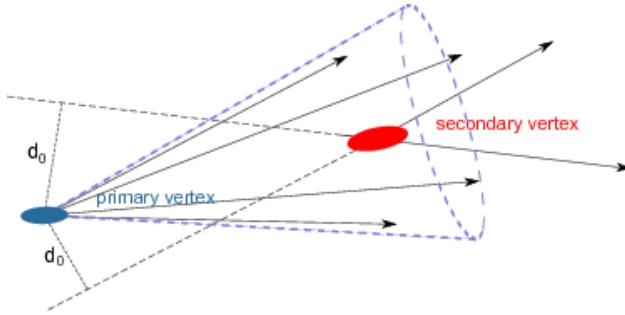

Figure 5.6: Schematic view of the tracks in a *b*-jet [43].

There are several methods used to tag a jet as coming from a *b* quark; this analysis uses the DL1 high level tagger [44] that is based on an artificial deep neural network. Neural networks are discussed in detail in Section 6.4. DL1 not only tags *b*-jets, but also outputs the probability for a jet to be initiated from a charm or light flavor quark. The DL1 tagger has over 20 input variables, including the p_T and η of jets [Find reference about DL1 inputs.](#) [45]. The analysis discussed in this dissertation uses a fixed cut working point that corresponds to an average efficiency of 70% for *b*-jets in $t\bar{t}$ events. [Quote light and c miss-tag rates.](#)

5.6 τ Identification

One of the most important particles in the final state of the search discussed in this dissertation is the τ lepton. The decay channels of τ leptons make them difficult to reconstruct. A τ lepton can decay to hadrons, an electron, or a muon; in each decay mode, at least one neutrino is also present. The analysis discussed in this dissertation only considers τ leptons that have decayed hadronically. The hadronic decay mode consists of 1 or 3 charged hadrons (π^\pm), a neutrino, and possible neutral hadrons (π^0). A τ lepton decaying in this manner within the ATLAS detector leaves 1 or 3 tracks in the ID and collimated showers of energy in the calorimeters; the neutrino does not interact with the ATLAS detector, therefore no direct signature is left behind. Reconstruction is done on the visible part of the hadronically decaying τ lepton, further referred to as $\tau_{had-vis}$ in the rest of this dissertation.

The $\tau_{had-vis}$ candidates start with an anti- k_t jet seed with $E_T > 10$ GeV in the calorimeter; tracks and topoclusters within $\Delta R = 0.2$ are added to the $\tau_{had-vis}$ candidate. The axis of the original jet seed is redefined in the direction of the $\tau_{had-vis}$ candidate and calibration is done at the $\tau_{had-vis}$ scale [46]. An overlap removal is done to ensure the $\tau_{had-vis}$ candidate is isolated from electrons and muons. Tracks are required to have $E_T > 30$ GeV, $|\eta| < 2.3$ and strictly either 1 or 3 tracks. A $\tau_{had-vis}$ candidate is referred to as 1-prong or 3-prong based on the associated number of tracks. To discern $\tau_{had-vis}$ objects from quark-initiated and gluon-initiated jets a Recurrent Neural Network (RNN) is used [47]. The search described in this analysis uses a medium WP that corresponds to 75% identification efficiency for 1-prong and 60% for 3-prong in $\gamma \rightarrow \tau\tau$ collision events.

5.7 E_T^{miss}

The final SM particle in the reconstruction scheme is the neutrino². The presence of a neutrino, or another minimally interacting particle, can be inferred through the calculation of E_T^{miss} ³; which takes advantage of the initial collision having a small momentum in the transverse plane ($p_T \simeq 0$). The initial momentum in the z direction (along the beamline) cannot be known due to the composite nature of the colliding protons and the associated PDFs of their components.

The calculation of E_T^{miss} in the ATLAS detector is defined as

$$E_T^{\text{miss}} = -\sum E_T = \sum p_T^\mu + \sum p_T^e + \sum p_T^\gamma + \sum p_T^\tau + \sum p_T^{\text{jets}} + \sum p_T^{\text{soft}} \quad (5.4)$$

where the p_T^{soft} term comes from soft tracks that are not associated with any physics objects [48]. The analysis discussed in this dissertation uses E_T^{miss} triggers in one of the subchannels to select events and is described in Chapter 6.

²The W, Z and gluon do not have long enough lifetimes to leave signatures within the ATLAS detector volume. Instead, their presence is inferred through their decay products

³The choice of E_T^{miss} to represent missing transverse momentum is a common nomenclature. Other choices include p_T^{miss} , MET, and et miss.

CHAPTER 6

SEARCH FOR CHARGED HIGGS BOSONS

This chapter details a search for a charged Higgs boson decaying to a hadronically decaying tau lepton and a neutrino; the phenomenology is discussed in Section 2.3. The search contains two subchannels, $\tau + \text{jets}$ and $\tau + \ell$ based on the decay of the associated top quark in the collision event. The $\tau + \text{jets}$ subchannel ($t \rightarrow Wb$, $W \rightarrow q\bar{q}$) has a higher branching fraction, leading to higher sensitivity at larger m_{H^\pm} values. The $\tau + \ell$ subchannel ($t \rightarrow Wb$, $W \rightarrow \ell\nu$) has a much lower branching fraction, but takes advantage of single-lepton triggers which enhance background suppression of QCD jet $\rightarrow \tau$ fakes. This leads to an increased sensitivity at lower m_{H^\pm} values. The extra neutrino in the $\tau + \ell$ decay mode creates extra difficulties in separating signal from background in this subchannel by adding a significant contribution to the E_T^{miss} calculation for the event.

The search described by this dissertation uses a profile likelihood ratio as the test statistic in a simultaneous fit in two Control Regions (CRs) and three Signal Regions (SRs). The discriminating variable is chosen to be the output score distribution of a Multivariate Analysis Technique (MVA). In the previous publication described in Section 2.3.1 several BDT were used, binned in m_{H^\pm} ; this analysis uses a PNN to classify events as signal-like or background-like.

This chapter discusses in detail the entire analysis, including the signal signatures, event selections, analyzed datasets, modeling of backgrounds, training and evaluation of classifiers, studies of systematic uncertainties, and results.

6.1 Signature and Event Selection

As shown in Figure 2.4, the production of the H^\pm is dependent on its mass m_{H^\pm} . Table 6.1 shows the production mechanisms for m_{H^\pm} values in bins of the top quark mass m_t as well as the main decay mode (and theoretical constraints), and the main source of background. Three mass ranges are defined, low mass $80 \leq m_{H^\pm} \leq 130$ GeV, intermediate mass $140 \leq m_{H^\pm} \leq 190$, and high mass $200 \leq m_{H^\pm} \leq 3000$ GeV. The two subchannels have similar signal signatures with a hard-scatter source of E_T^{miss} , one $\tau_{\text{had-vis}}$, and at least 1 b -jet from the associated top decay. In the $\tau + \ell$ subchannel there is an extra requirement of a lepton (e or μ). Due to the variable amount of energy available to the final state products based on m_{H^\pm} the event topology changes as a function of m_{H^\pm} . As described in Section ??, classifiers are trained and evaluated in m_{H^\pm} bins to account for the varying event topology.

| H^\pm Mass | Production Mechanism | Decay | Main Background |
|------------------------|---|--|-------------------------|
| $m_{H^\pm} < m_t$ | double-resonant $t \rightarrow H^\pm b$ (LO) | $H^\pm \rightarrow \tau^\pm \nu_\tau$ (low $\tan \beta \implies H^\pm \rightarrow cs$ or $H^\pm \rightarrow cb$) | $t\bar{t}$, single-top |
| $m_{H^\pm} \simeq m_t$ | non-resonant $t \rightarrow H^\pm b$ (LO) interferences taken into account | $H^\pm \rightarrow \tau\nu$ | $t\bar{t}$, single-top |
| $m_{H^\pm} > m_t$ | single-resonant $gg \rightarrow tbH^\pm$ (NLO) | $H^\pm \rightarrow tb$ ($\cos(\beta - \alpha) \simeq 0$ and large $\tan(\beta) \implies H^\pm \rightarrow \tau\nu$ $BR(H^\pm \rightarrow \tau^\pm \nu_\tau) \simeq 10 - 15\%$) | multi-jet |

Table 6.1: H^\pm production mechanisms based on m_{H^\pm} , dominant H^\pm decay mode, and the main background associated with the diagram.

6.1.1 Object Definitions

Table 6.2 shows the identification requirements on all objects used in the analysis. In both subchannels $\tau_{had-vis}$ candidates are required to fit the medium working point described in Section 5.6 that corresponds to a 75% efficiency for 1-prong and 60% efficiency for 3-prong $\tau_{had-vis}$ identification, an $|\eta|$ cut of < 2.3 that also excludes the gap and crack region of the ATLAS calorimeters at $1.37 < |\eta| < 1.52$, and an overlap removal with electrons. For the $\tau+jets$ subchannel, the $\tau_{had-vis} p_T$ is required to be greater than 40 GeV and greater than 30 GeV for the $\tau + \ell$ subchannel. Although muons and electrons are not part of the $\tau+jets$ signal final state, a loose identification and isolation requirement is used to veto events; while the $\tau + \ell$ subchannel requires there to be either an electron or a muon that passes the tight identification and isolation requirements as well as a p_T above 30 GeV. The jets in candidate events are required to have greater than 25 GeV in p_T and are made with the anti- k_t algorithm with R=0.4. Jets tagged as b -jets are done so at a 70% efficient working point using the DL1r tagger described in Section 5.5.1.

| Object | $\tau+jets$ | $\tau + \ell$ |
|------------------|--|--|
| $\tau_{had-vis}$ | Leading reconstructed τ (regardless of its ID), mediumID*, $p_T > 40$ GeV, $ \eta ^{***} < 2.3$, e OLR | Leading reconstructed τ (regardless of its ID), mediumID*, $p_T > 30$ GeV, $ \eta ^{***} < 2.3$, e OLR |
| e | LoseLLH, $p_T > 20$ GeV, $ \eta ^{***} < 2.47$, Loose isolation, IP cuts | TightLLH, $p_T > 30$ GeV, $ \eta ^{***} < 2.47$, Tight isolation, IP cuts |
| μ | LooseID, $p_T > 20$ GeV, $ \eta < 2.5$, Loose isolation, IP cuts | TightID, $p_T > 30$ GeV, $ \eta < 2.5$, Tight isolation, IP cuts |
| jet | AntiKt4EMPFlow, $p_T > 25$, GeV $ \eta < 2.5$, JVT** > 0.59, Btag=70%, DL1r | AntiKt4EMPFlow, $p_T > 25$ GeV, $ \eta < 2.5$, JVT** > 0.59, Btag=70%, DL1r |

Table 6.2: Definitions of physics objects used in this analysis.

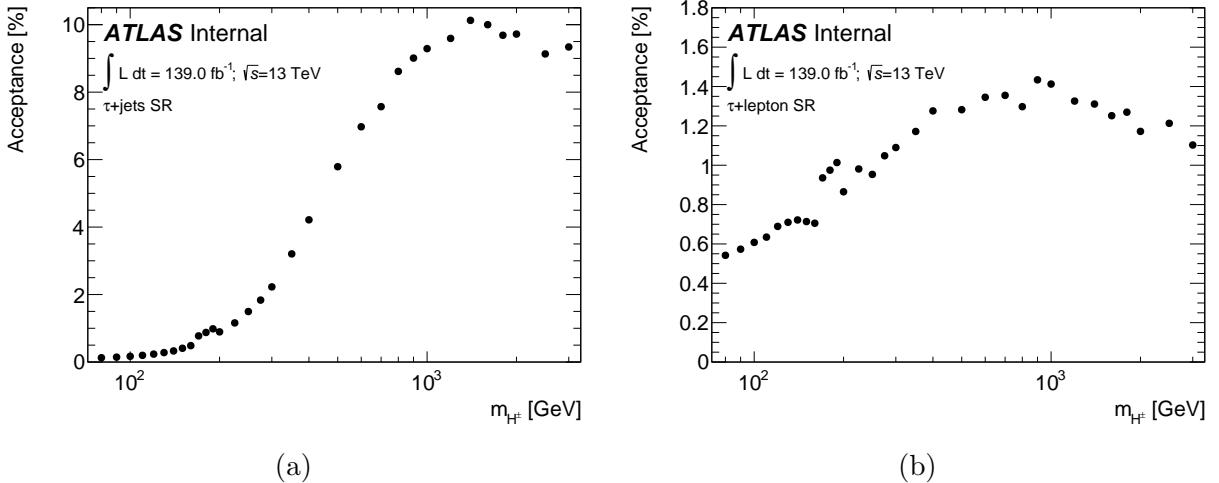

6.1.2 Event Selections

Each subchannel signal region has stricter requirements than the object definitions described in Section 6.1.1. Table 6.3 details these selections. The channels differ in the triggers used; the $\tau + \text{jets}$ subchannel relies on E_T^{miss} triggers while the $\tau + \ell$ subchannel relies on single lepton triggers. Due to the difficulty of separating signal from background and the large amount of background, the $\tau + \text{jets}$ subchannel has a higher p_T cut on the $\tau_{\text{had-vis}}$ of 40 GeV as opposed to the $\tau + \ell$ value of 30 GeV. In addition, a higher value of E_T^{miss} of 150 GeV is required for the $\tau + \text{jets}$ subchannel compared to 50 GeV in the $\tau + \ell$ subchannel. In the $\tau + \text{jets}$ subchannel a value of 50 GeV is also required of the transverse mass m_T defined as

$$m_T = \sqrt{2p_T^\tau E_T^{\text{miss}}(1 - \cos\Delta\phi_{\tau, E_T^{\text{miss}}})} \quad (6.1)$$

The $\tau + \ell$ has no such requirement, but does require the $\tau_{\text{had-vis}}$ and lepton to have opposite electromagnetic charge. A set of orthogonal CRs are defined for each subchannel to verify proper background modelling and are described in Section 6.3. The acceptance of signal in the signal regions defined in Table 6.3 is shown in Figure 6.1. Due to the larger branching fraction of $t \rightarrow W + b; W \rightarrow q\bar{q}$ as opposed to $t \rightarrow W + b; W \rightarrow \ell + \nu$ the $\tau + \text{jets}$ subchannel has a factor of 10 larger signal acceptance than the $\tau + \ell$ subchannel. In both channels, the signal acceptance decreases for m_{H^\pm} values > 1000 GeV. This is an artifact of objects becoming boosted, meaning their decay products are extremely collimated, resulting in lower efficiencies for object identification.

| $\tau + \text{jets SR}$ | $\tau + \ell \text{ SR}$ |
|---|---|
| E_T^{miss} Trigger | Single lepton triggers (e or μ) |
| 1 $\tau_{\text{had-vis}}$; $p_T^\tau > 40$ GeV | 1 $\tau_{\text{had-vis}}$; $p_T^\tau > 30$ GeV |
| 0 ℓ (e or μ) ; $p_T^\ell > 20$ GeV | 1 ℓ (e or μ) ; $p_T^\ell > 30$ GeV |
| ≥ 3 jets ; $p_T^j > 25$ GeV | ≥ 1 jet ; $p_T^j > 25$ GeV |
| ≥ 1 b -jets; $p_T^{b\text{-jet}} > 25$ GeV | ≥ 1 b -jets; $p_T^{b\text{-jet}} > 25$ GeV |
| $E_T^{\text{miss}} > 150$ GeV | $E_T^{\text{miss}} > 50$ GeV |
| $m_T(\tau, E_T^{\text{miss}}) > 50$ GeV | Opposite sign τ and ℓ |

Table 6.3: $\tau + \text{jets}$ and $\tau + \ell$ signal region definitions.Figure 6.1: Signal acceptance as a function of the charged Higgs boson mass for both the $\tau + \text{jets}$ (a) and $\tau + \ell$ subchannels (b).

6.2 Datasets

This analysis uses the full Run-2 ATLAS dataset collected between 2015 and 2018 corresponding to $139.0 \pm 2.4 \text{ fb}^{-1}$ [49]. The datasets used are required to be included in the ATLAS “Good Run Lists” (GRLs), meaning they have passed nominal data quality checks with all detector subsystems operating within normal conditions. Further event cleaning is

applied that removes events in which a reconstructed jet originated from detector noise or non-collision backgrounds. The collection of data throughout Run-2 can be seen in Figure 3.4.

6.2.1 Signal Modeling

MC simulations of H^\pm signal events are generated at varying orders dependent on m_{H^\pm} . In all cases, the 2HDM Type II model described in Section 2.2.2 is assumed and the generator MadGraph is used. The lower mass range corresponding to $m_{H^\pm} < 140$ GeV where a H^\pm takes the place of a W^\pm in a top decay is generated at LO. The intermediate mass range of $140 \leq m_{H^\pm} < 200$ GeV is generated at LO, taking into account the non-resonant, single-top resonant and double-resonant diagrams and their interferences. In this mass range, the final state contains one H^\pm , one W^\pm , and two b quark. For charged Higgs masses of 200 GeV and above, the H^\pm is produced in association with a top quark and is generated at NLO. The Powheg-box v2 [30, 31] generator is used with the NNPDF3.0 NLO PDF [50] set in the matrix element calculations to generate $t\bar{t}$ and single top-quarks in the W t- and s-channels. In all cases, the parton generator is interfaced with Pythia v8.230 [29] with the NNPDF2.3 LO PDF [51] using the A14 underlying event tuning parameters [52]. Table 6.4 shows the cross section and raw number of events generated for each m_{H^\pm} point for both subchannels.

6.3 Background Modeling

The main sources of backgrounds are shown in Table 6.5, separated between backgrounds with a prompt $\tau_{had-vis}$ in the hard scatter process and those that arise from the misidentification of other physics objects as a $\tau_{had-vis}$. The cross section of all simulated background

Table 6.4: For each H^\pm mass the generator cross-section ($\sigma \times BR(H^\pm \rightarrow \tau^\pm \nu_\tau)$) is given, as well as the number of generated events for both $\tau + \ell$ and $\tau + \text{jets}$ subchannels.

samples and the relevant generators can be seen in Table 6.6. Control regions that are designed to be orthogonal to the signal region are created for both subchannels in order to study the modeling of the backgrounds. These control regions are defined by the cuts in Table 6.7 ($\tau + \text{jets}$) and Table 6.8 ($\tau + \ell$). For the $\tau + \ell$ subchannel the Same Sign and b-veto control regions are further split into two control regions, one that requires a μ in the event and another that requires an electron.

| Backgrounds w/ prompt $\tau_{had-vis}$ | Backgrounds w/ fake τ |

Table 6.8: Control region definitions for the $\tau + \ell$ subchannel.

are well modeled in MC simulations and are reweighted with scale factors provided by the ATLAS τ combined performance group. The mass of the $\tau_{had-vis}$ electron system can be seen in Figure 6.2 as verification of fake $\ell \rightarrow \tau$ modeling. However, fakes due to $j \rightarrow \tau$ misidentification are not well modeled in MC simulations due to a poor misunderstanding of systematic uncertainties associated with the fake $\tau_{had-vis}$ object and limited statistics of simulated events. Instead, a data driven method is used to extract a scaling constant referred to as a fake factor.

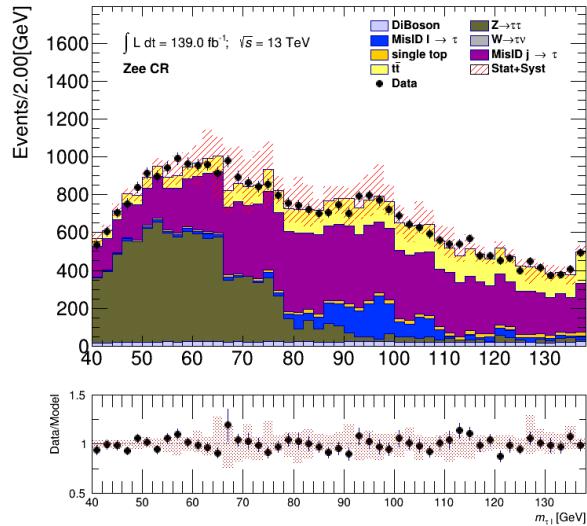

Figure 6.2: Mass of τ - e system in the Zee control region. All systematics except for $t\bar{t}$ theory uncertainties are included.

In the $\tau + \ell$ final state a significant portion of $j \rightarrow \tau$ fakes come from misidentifying $\tau_{had-vis}$ candidates in W+Jets events that contain a true ℓ in the W decay and have a misidentified jet as a $\tau_{had-vis}$. Fakes of this manner also arise from QCD-like multi-jet interactions. The FF method used to estimate the amount of expected fake $\tau_{had-vis}$ objects that pass the $\tau_{had-vis}$ identification procedure is described in Section 5.6. This method applies weights, or fake factors, to a subset of "anti- $\tau_{had-vis}$ " objects that have failed the selection and identification criteria in the signal region. A control region is defined to be rich in anti- $\tau_{had-vis}$ objects,

where the $\tau_{had-vis}$ candidates fail the loose τ working point but have a small, non-zero τ identification RNN score. The FF and number of events with misidentified $\tau_{had-vis}$ objects (N^τ) are defined as:

$$\begin{aligned} FF &= \frac{N^{\tau-id}}{N^{anti-\tau-id}} \\ N_{fakes}^\tau &= N_{fakes}^{anti-\tau} \times FF \end{aligned} \quad (6.2)$$

Both of these values are then corrected for $\tau_{had-vis}$ candidates matching a true hadronic τ at generator level:

$$\begin{aligned} N^{\tau-id} &= N^{\tau-id}(Data) - N^{\tau-id}(MC) \\ N_{fakes}^{anti-\tau} &= N^{anti-\tau}(Data) - N_{true}^{anti-\tau}(MC) \end{aligned} \quad (6.3)$$

Two CRs are created, one to capture the multi-jet (MJ) fakes and the other to study the W+jets fakes. The MJ CR uses the $\tau+jets$ signal region definition with an additional b-veto and an $E_T^{\text{miss}} < 80$ GeV cut. The W+jets CR¹ uses the $\tau + \ell$ signal region definition with a b-veto, no E_T^{miss} cut, and a cut on the transverse mass of the $\ell-E_T^{\text{miss}}$ system of $60 < m_T(\ell, E_T^{\text{miss}}) < 160$ GeV. The FF in the signal region is defined as

$$FF_{sig} = \alpha_{MJ} \times FF_{MJ} + (1 - \alpha_{MJ}) \times FF_{W+jets} \quad (6.4)$$

where α is taken from a template fit of the τ -ID score distributions of the anti- τ s using template shapes from the anti- τ distributions in the MJ and W+jets control regions. In the signal regions, the number of events containing fake- $\tau_{had-vis}$ candidates is defined as

$$N_{fake-\tau} = FF_{sig} \times N_{anti-\tau} \quad (6.5)$$

¹This W+Jets CR is not the one defined in Table 6.7. This is a new region used to extract the fake factors.

Figure 6.3 shows FF plotted in each control region for 1-prong and 3-prong $\tau_{had-vis}$ binned in $p_T\tau$; extracted α values and their fits can be seen in Appendix B.

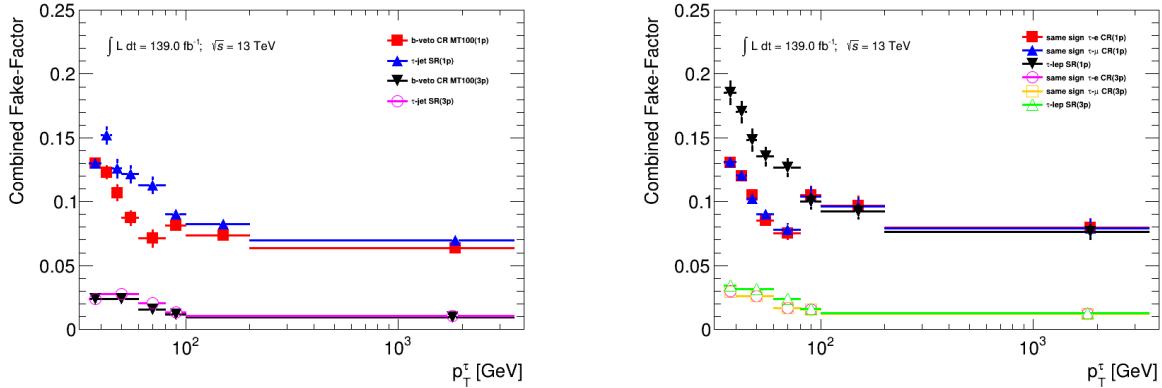

Figure 6.3: Combined FF for the $\tau+jets$ b-veto $m_T > 100$ control region, $\tau+jets$ signal region, $\tau+electron(muon)$ with same-sign control region and the $\tau + \ell$ signal region. Error bars represent systematic uncertainties of the method.

To verify background modeling, the E_T^{miss} distributions in each of the control regions are plotted with final scale factors including fake factors in Figure 6.4 ($\tau+jets$) and Figure 6.5 ($\tau + \ell$). These plots include a ratio of reconstructed data events and simulated MC events bin by bin to ensure proper modeling across variable shapes. More background modeling plots can be seen in Appendix C.

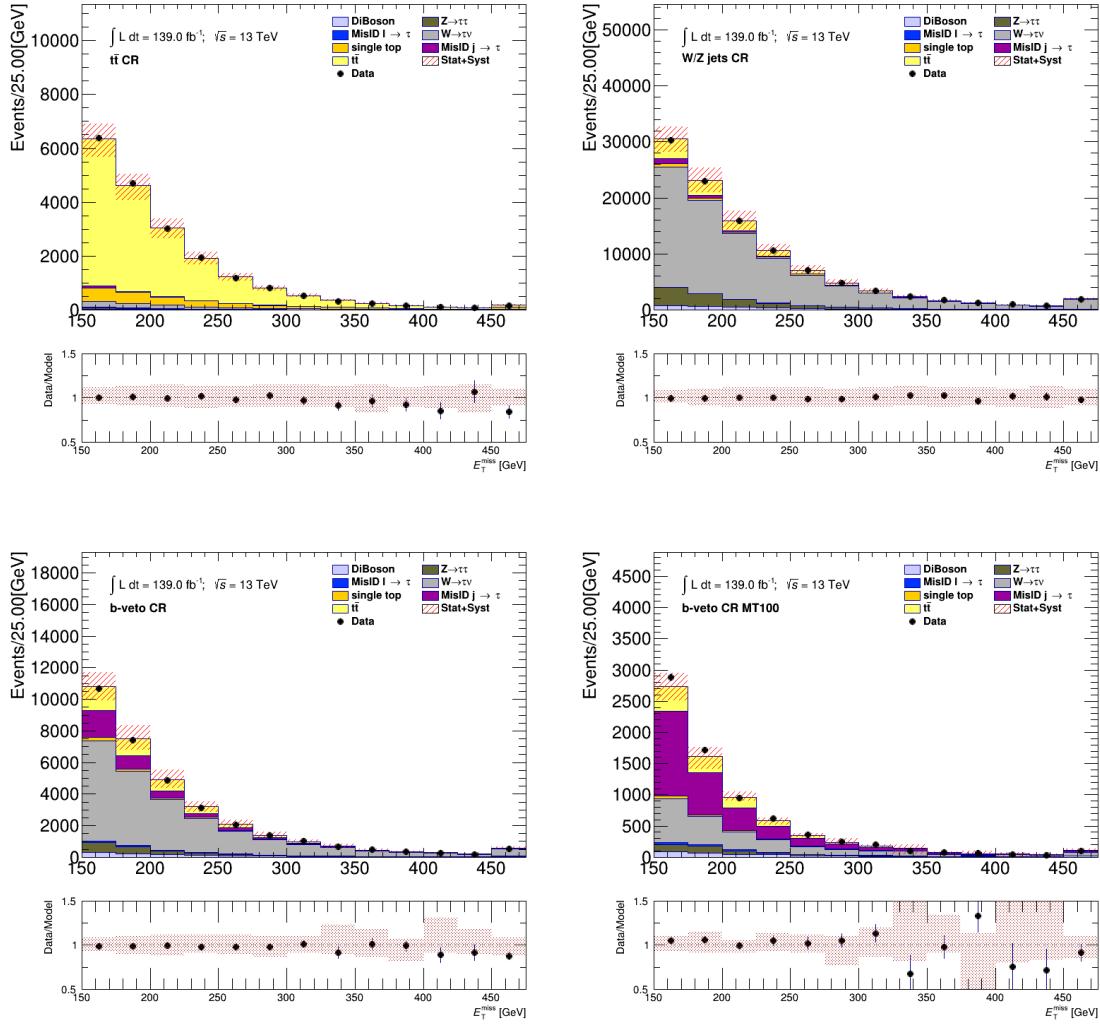

Figure 6.4: Comparison between the predicted and the measured E_T^{miss} distributions in various control regions defined for the $\tau + \text{jets}$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

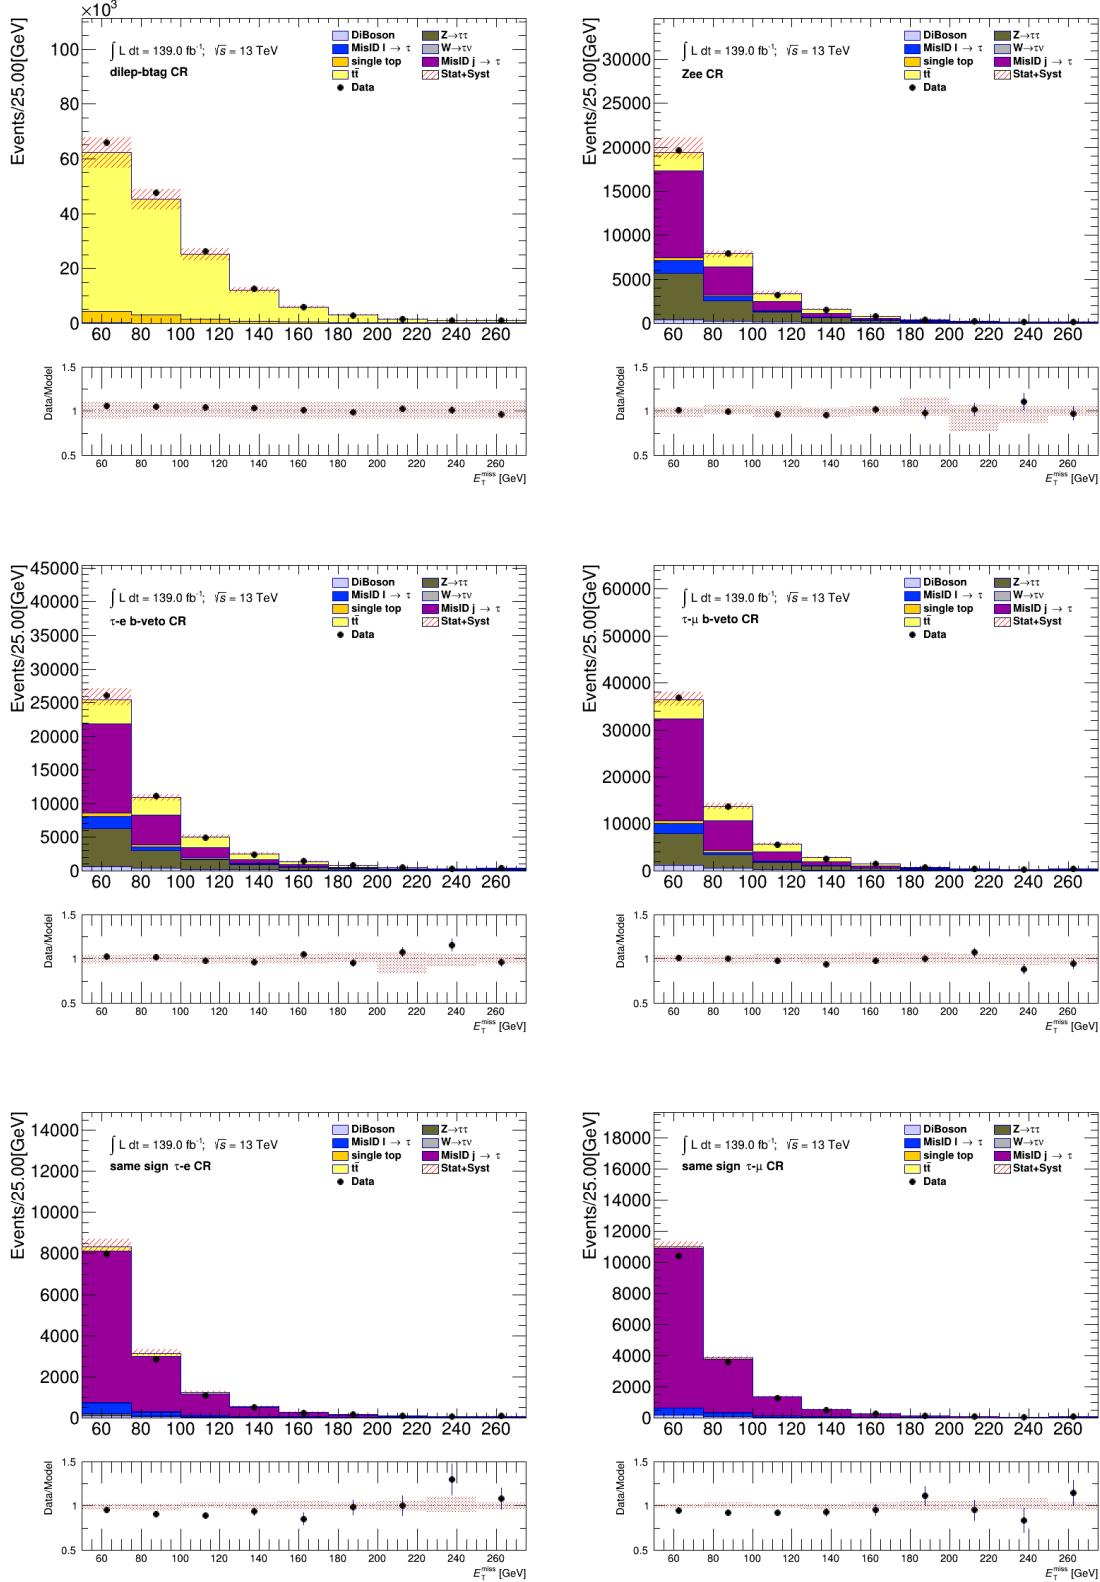

Figure 6.5: Comparison between the predicted and the measured E_T^{miss} distributions in various control regions defined for the $\tau + \ell$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

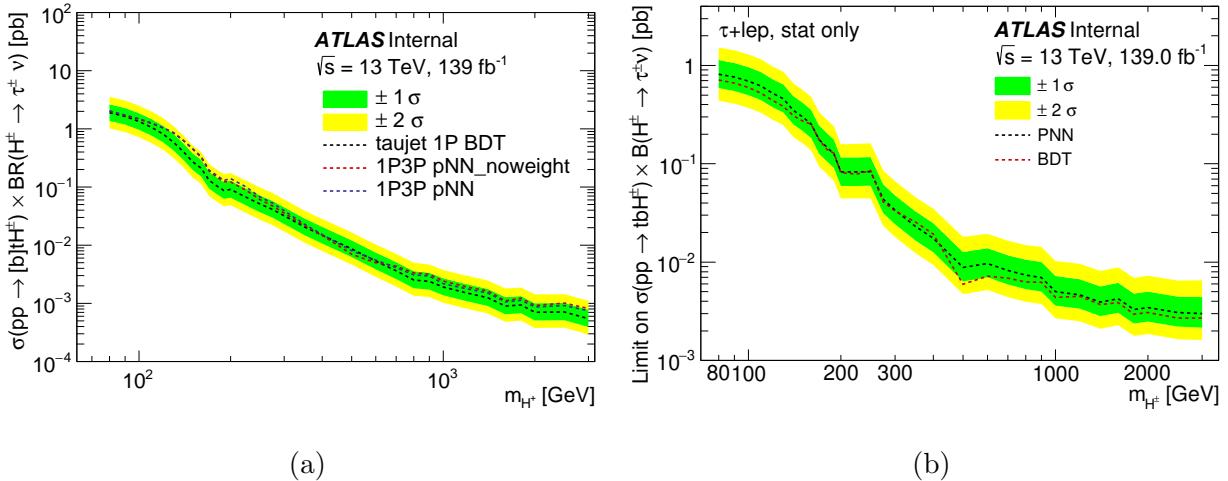

Figure 6.6: Comparison of performance of an optimized BDT and an unoptimized PNN on expected limits on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ in the $\tau + \text{jets}$ (a) and $\tau + \ell$ (b) signal regions.

6.4 Multivariate Analysis Techniques

Once variables distributions are properly scaled and data/MC agreement is verified, multivariate analysis techniques are employed to separate signal-like events from background-like events in the signal regions. In the previous publication (described in Section 2.3.1), BDTs binned in m_{H^\pm} were used as the classifier, this publication use one PNN for the entire m_{H^\pm} spectrum. BDTs excel at separating linear correlations, whereas neural networks take advantage of nonlinear correlations. In the case of a PNN the parameterized variable, here m_{H^\pm} , is taken as an input to the network in addition with other input variables. PNNs offer the advantage of having one classifier model that can evaluate at any m_{H^\pm} value by learning how the signal event topology changes as m_{H^\pm} varies [53]. For illustrative purposes, expected limits on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ in both subchannels is shown comparing an optimized BDT and an unoptimized PNN in Figure 6.6. It is seen that the PNN performs similarly to the BDTs used in the previous analysis. A PNN was chosen as the discriminator.

A Neural Network (NN) is a computing system loosely inspired by the human brain. NNs combine adaptive nonlinear basis functions in an attempt to perform a task, classification in the context of this dissertation. A NN contains layers of nodes connected to each other with an associated weight and threshold. As long as a node has output greater than the given threshold value, data will flow through that node. Otherwise, that node is not activated and data are not sent to the next layer. The NN as a whole relies on a process called training where the node weights are varied, an accuracy is calculated based on a given loss function, the weights are then varied again and the process repeats. This is done until a preferred accuracy is reached; the final node weights are saved and new data can be evaluated. A diagram of a PNN can be seen in Figure 6.7, where the parameterized input is labeled as θ . The learned function of a NN can be written as:

$$y(x) = w_0^2 + \sum_{m=1}^M [w_m^2 \cdot h(w_{0m}^1 + \sum_{k=1}^D w_{km}^1 x_k)] \quad (6.6)$$

where w is the neuron weights, M is the number of basis functions being combined, D is the number of inputs and h is the activation function.

This analysis uses four PNNs, events with 1-prong τ and 3-prong τ are divided into separate datasets within both subchannels.

6.4.1 Training

The training of the PNNs used in this dissertation are done with the Keras [54] library using the TensorFlow [55] library as backend. In order to increase the significance of training statistics and protect from overtraining, the k -fold method is used. Overtraining occurs when a NN has been fine tuned to have a high accuracy with a specific dataset and does not generalize to other datasets. To protect against this, dropout is used [56]. The k -fold method

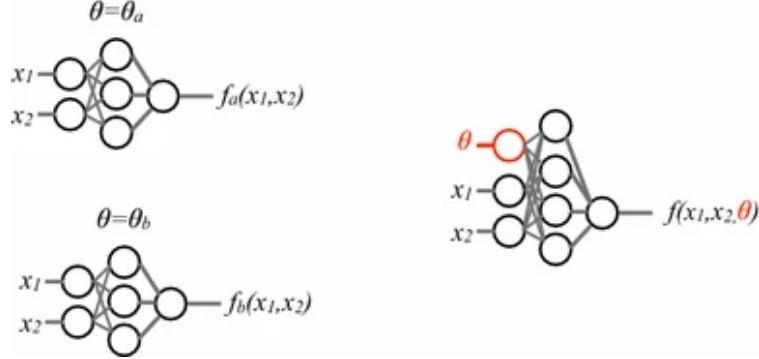

Figure 6.7: *Left*, individual networks with input variables (x_1, x_2) , each trained with examples with a single value of some parameter $\theta = \theta_a, \theta_b$. The individual networks are purely functions of the input variables. Performance for intermediate values of θ is not optimal nor does it necessarily vary smoothly between the networks. *Right*, a single network trained with input variables (x_1, x_2) as well as input parameter θ ; such a network is trained with examples at several values of the parameter θ [53].

| | Fold 1 | Fold 2 | Fold 3 | Fold 4 | Fold 5 | Background |
|-------------|------------|------------|------------|------------|------------|------------|
| Partition 1 | Evaluation | Train | Train | Train | Train | Fold 1 |
| Partition 2 | Train | Evaluation | Train | Train | Train | Fold 2 |
| Partition 3 | Train | Train | Evaluation | Train | Train | Fold 3 |
| Partition 4 | Train | Train | Train | Evaluation | Train | Fold 4 |
| Partition 5 | Train | Train | Train | Train | Evaluation | Fold 5 |

Figure 6.8: The k -fold method for $k = 5$ [57].

divides input training samples into k equally populated subsets. The k -th subset is trained on the other $k - 1$ subsets and evaluated on the k -th subset. Figure 6.8 shows a pictorial representation of the k -fold method. $k = 5$ is chosen in this analysis.

A single PNN training is performed on all m_{H^\pm} values at once, with the m_{H^\pm} value being taken as an input variable. For signal events, the m_{H^\pm} value from the MC generator is given; background events are replicated 32 times (the number of simulated m_{H^\pm} points is 32) and each m_{H^\pm} value is given for each set. To avoid biasing the training due to varying statistics at each m_{H^\pm} value, the background events are weighted by a factor of $w = N_S^i/N_B^i$ where i corresponds to a given m_{H^\pm} value and N_S^i and N_B^i are the number of signal and background

events, respectively. When the PNN is evaluated, the m_{H^\pm} value is assumed and the output is used as the discriminant at that m_{H^\pm} .

6.4.2 Input Variables Selection

The choice of input variables to the PNNs is critical to the performance of the analysis. Several sets of variables were compared using expected limits as the figure of merit. All studies were performed in the $\tau + \ell$ signal region, as this region proves the most difficult challenge to separate signal-like events from background-like events. So called low level variables, consisting of the four vector components of the main physics objects in each event, were compared against high level variables; high level meaning they are calculated quantities from the low level variables. Tables of the low level and high level variables are shown in Table 6.9.

The variable $m_{H^\pm}^{Truth}$ corresponds to the m_{H^\pm} value the training and evaluation is performed at. In both cases, the variable Υ is used. Υ is a measure of the $\tau_{had-vis}$ polarization, computed by taking the asymmetry of energies carried by the charged and neutron pions from the 1-prong τ decay measured in the laboratory frame. Υ is defined as

$$\Upsilon = \frac{E_T^{\pi^\pm} - E_T^{\pi^0}}{E_T^\tau} \approx 2 \frac{p_T^{\tau-track}}{p_T^\tau} - 1 \quad (6.7)$$

where $p_T^{\tau-track}$ is the transverse momentum of the track associated with the 1-prong $\tau_{had-vis}$ candidate. As such, Υ is only defined for 1-prong $\tau_{had-vis}$ candidates. As demonstrated in the previous analysis, Υ provides a large contribution to signal-backgrounds separation at charged Higgs masses below 400 GeV [8].

An estimate of the impact of low level vs high level variables on the expected limits on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ is shown in 6.9. The set of low level variables was chosen

Low Level Input Variables

| | | | |
|----------------------------|----------------------------|----------------|-------------|
| p_T^τ | η^τ | ϕ^τ | E^τ |
| p_T^ℓ | η^ℓ | ϕ^ℓ | E^ℓ |
| p_T^{b-jet} | η^{b-jet} | ϕ^{b-jet} | E^{b-jet} |
| p_T^{jet} | η^{jet} | ϕ^{jet} | E^{jet} |
| E_T^{miss} | $\phi^{E_T^{\text{miss}}}$ | $p_T^{j_1}$ | Υ |
| $m_{H^\pm}^{\text{Truth}}$ | | | |

(a) Low level variables

| $m_{H^\pm}^{\text{Truth}}$ |

(b) High level variables

Table 6.9: List of low level (a) and high level (b) kinematic variables used as input to the PNN in the $\tau + \ell$ subchannel. $\Delta\phi_{X, \text{miss}}$ denotes the difference in azimuthal angle between a reconstructed object X ($X = \tau, b - jet, \ell$) and the direction of the missing transverse momentum.

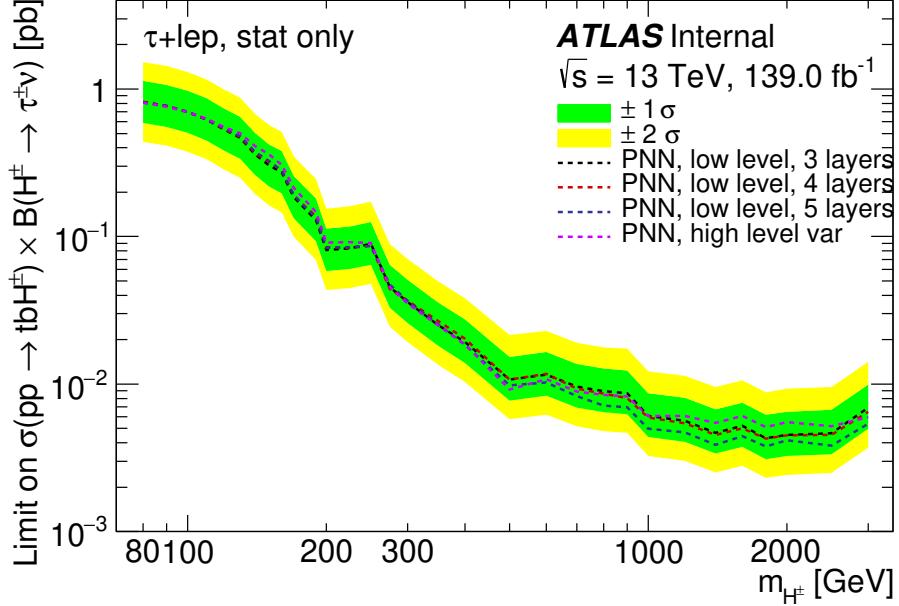

Figure 6.9: Expected limits comparing a set of high level variables and low level variables with various depths in the PNN architecture. X layers refers to the number of layers in the PNN.

as performance was similar in low m_{H^\pm} and greater in high m_{H^\pm} . A optimization of the number of layers in the PNN and several other parameters of the PNN is discussed in detail in Section 6.4.3.

6.4.3 Hyperparameter Optimization

In order to optimize the PNN, a scan of hyperparameters and network architecture was done, referred to as HPO. A calculated AUC was used as the figure of merit. As in the normal training scheme, the k -fold method with $k = 5$ was used to keep background modelling and classifier training statistically independent. To prevent overtraining, the early stopping method was used with $\Delta_{min} = 0.00001$ and a patience of 10, with the best weights kept to

calculate the AUC. To optimize for PNN performance in low H^\pm mass points, a separate average taking into account only H^\pm mass values between 80 and 500 GeV was used as the final figure of merit. In an effort to keep the computational needs low, several small grids of hyperparameters and architecture structures were scanned. Tables 6.10 - 6.14 show the hyperparameter grids that were searched. Here, width refers to the number of neurons per layer and depth is the number of layers. The final hyperparameter from each grid search is highlighted in red. The results of the final grid search can be seen in Tables 6.15 and 6.16; the quoted errors are taken from the different k -folds. The AUC values for each m_{H^\pm} point for the final chosen model are shown in Figure 6.10.

| Parameter | | | |

Table 6.16: Average AUCs of final HPO grid. An error of 0 corresponds to only one job k-fold finishing training due to computational limits.

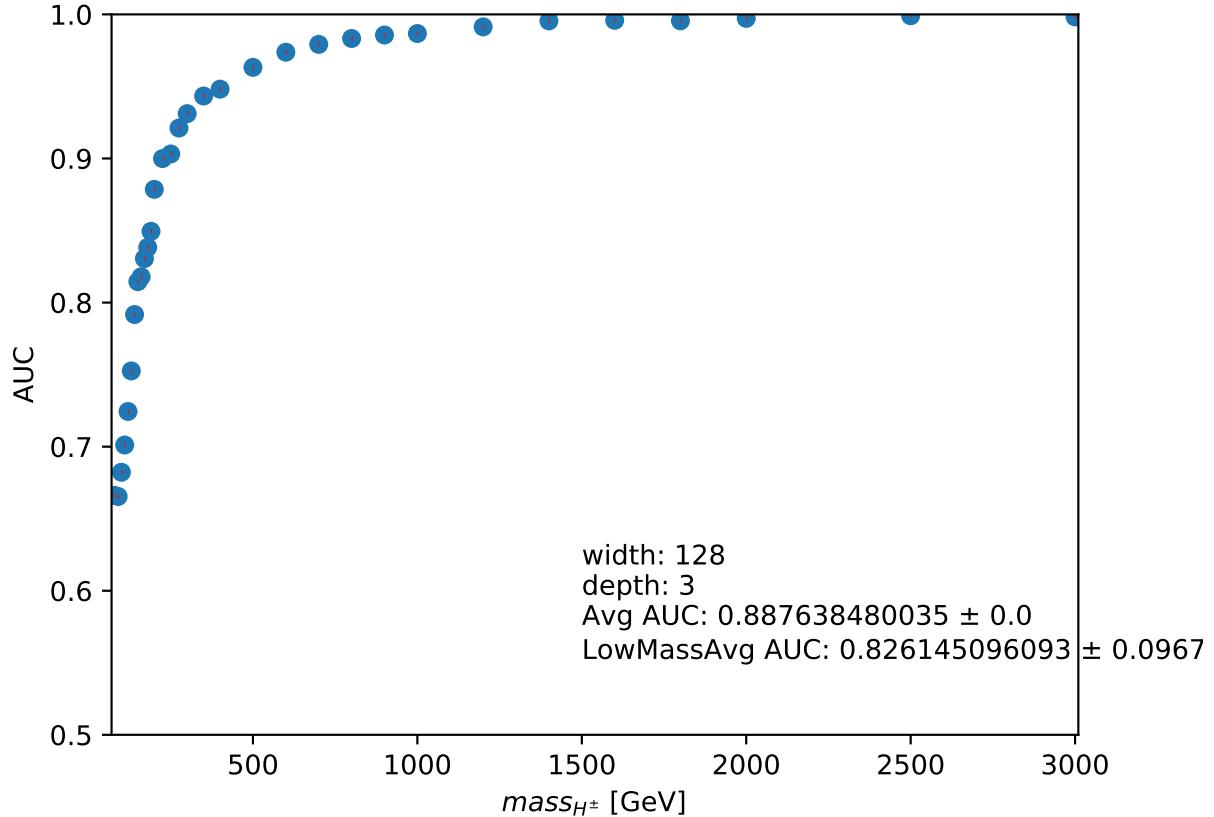

Figure 6.10: Final model AUC for each mass point. Individual points correspond to the AUC average over 5 kfolds.

The final model was chosen to have 128 neurons per layer with 3 layers, with the binary cross-entropy chosen as the loss function, a dropout of 0.1, LeakyReLU as the activation function with $\alpha = 0.05$. The LeakyReLU activation function is depicted in Figure 6.11, where the α value is the slope of the negative portion. Allowing negative weight values prevents neurons from becoming deactivated prematurely.

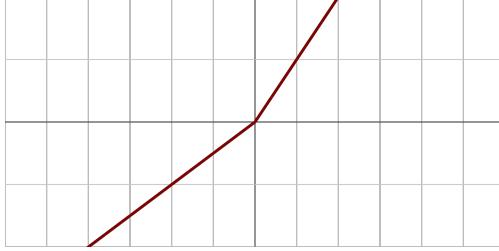

Figure 6.11: LeakyReLU activation function. The associated hyperparameter α is the slope of the negative portion of the function.

6.5 Systematic Uncertainties

Systematic uncertainties have a variety of sources and are discussed in detail here. Detector-related systematic uncertainties from the reconstruction and identification of leptons and $\tau_{had-vis}$ objects, simulation of the electron and muon triggers, reconstruction of E_T^{miss} , and energy/momentum scale and resolution of all physics objects are studied by varying selection cuts by ± 1 standard deviation. The difference in event yields is then taken as a systematic error and summed in quadrature with all other sources of error to give the final quoted errors. Systematic uncertainties arising from the data-driven fake factor method are shown in Table 6.17.

| Source of uncertainty | $\tau + \text{jets}$ | | $\tau + \ell$ | |
|--|----------------------|-------|-----------------|-------|
| | Effect on yield | Shape | Effect on yield | Shape |
| Fake factors: statistical uncertainties | 3.9% | ✓ | 3.2% | ✓ |
| Fake factors: True $\tau_{had-vis}$ in the anti- $\tau_{had-vis}$ CR | +3.4% -3.2% | ✓ | +4% -4.3% | ✓ |
| Fake factors: tau RNN Identification SF | 2.7% | ✓ | 2.7% | ✓ |
| Fake factors: α_{MJ} uncertainty | 3.6% | ✓ | 1.9% | ✓ |
| Fake factors: Smirnov transform | 0% | ✓ | 0% | ✓ |
| Fake factors: heavy flavor jet fraction | 5% | ✓ | 5% | ✓ |

Table 6.17: Effect on the shape variation and the yields of systematic uncertainties associated with the data-driven fake factor method, used to estimate the $j \rightarrow \tau$ background in the $\tau + \text{jets}$ and $\tau + \ell$ channel.

Table 6.18: Expected event yields for the backgrounds and a hypothetical H^\pm signal after applying all τ +jets selection criteria, and comparison with 139 fb^{-1} of data. All yields are evaluated prior to using the multivariate discriminant and applying the statistical fitting procedure. The values shown for the signal assume a charged Higgs boson mass of 170 GeV and 1000 GeV, with a cross-section times branching fraction $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ corresponding to $\tan\beta = 40$ in the hMSSM benchmark scenario. Statistical uncertainties are quoted. **Systematic uncertainties to be added.**

| Sample | Event yields $\tau_{had-vis} + \text{jets}$ | | |
|---|---|-------------|-----------|
| True τ_{had} | | | |

| Data | XXX | | |

Theoretical uncertainties for signal and $t\bar{t}$ background were considered in the last publication; at the time of writing this dissertation the simulations are being produced and therefore are not included.

Systematic % difference wrt nominal is being finalized. Add in when done.

6.6 Results

The expected event yields for backgrounds and signal² are summarized in Table 6.18 (τ +jets) and Table 6.19 ($\tau + \ell$).

The test statistic \tilde{q}_μ [58] is used to test the agreement of the data with the background-only and signal+background hypotheses. The test statistic is based on a profile likelihood

²At the time of writing, the analysis is still blinded so Data is not included.

Table 6.19: Expected event yields for the backgrounds and a hypothetical H^\pm signal after applying all $\tau + \ell$ selection criteria, and comparison with 139 fb^{-1} of data. All yields are evaluated prior to using the multi-variate discriminant and applying the statistical fitting procedure. The values shown for the signal assume a charged Higgs boson mass of 170 GeV and 1000 GeV, with a cross-section times branching fraction $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ corresponding to $\tan\beta = 40$ in the hMSSM benchmark scenario. Statistical uncertainties are quoted. **Systematic uncertainties to be added.**

| Sample | Event yields $\tau+e$ | Event yields $\tau+\mu$ |

ratio where the binned likelihood function $\mathcal{L}(\mu, \theta)$ is constructed as the product of Poisson probability terms over all bins and regions. The likelihood ratio is the ratio between the conditional maximum-likelihood estimator of the nuisance parameters, θ , for a given signal hypothesis μ and the unconditional maximum-likelihood estimator for μ and the nuisance parameters. \tilde{q}_μ is defined as:

$$\tilde{q}_\mu = \begin{cases} -2 \ln \frac{\mathcal{L}(\mu, \hat{\theta}(\mu))}{\mathcal{L}(0, \hat{\theta}(0))}, & \hat{\mu} < 0 \\ -2 \ln \frac{\mathcal{L}(\mu, \hat{\theta}(\mu))}{\mathcal{L}(\hat{\mu}, \hat{\theta})}, & 0 \leq \hat{\mu} \leq \mu \\ 0 & \hat{\mu} > \mu \end{cases} \quad (6.8)$$

The fit is performed on the PNN score distributions in the three signal regions, $\tau+\text{jets}$, $\tau+e$, $\tau+\mu$, and the dilepton-btag control region which is enriched in the dominant $t\bar{t}$ background. Pre-fit PNN score distributions are shown in Figures 6.12, 6.13, and 6.14. At the time of writing this dissertation, the analysis is still blinded. Assuming the fit agrees

with the background-only hypothesis expected limits of $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ are calculated. Exclusion limits are set at the 95% confidence level (CL) using the CL_s procedure [59]. The expected exclusion limits on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau\nu)$ can be seen in Figure 6.15.

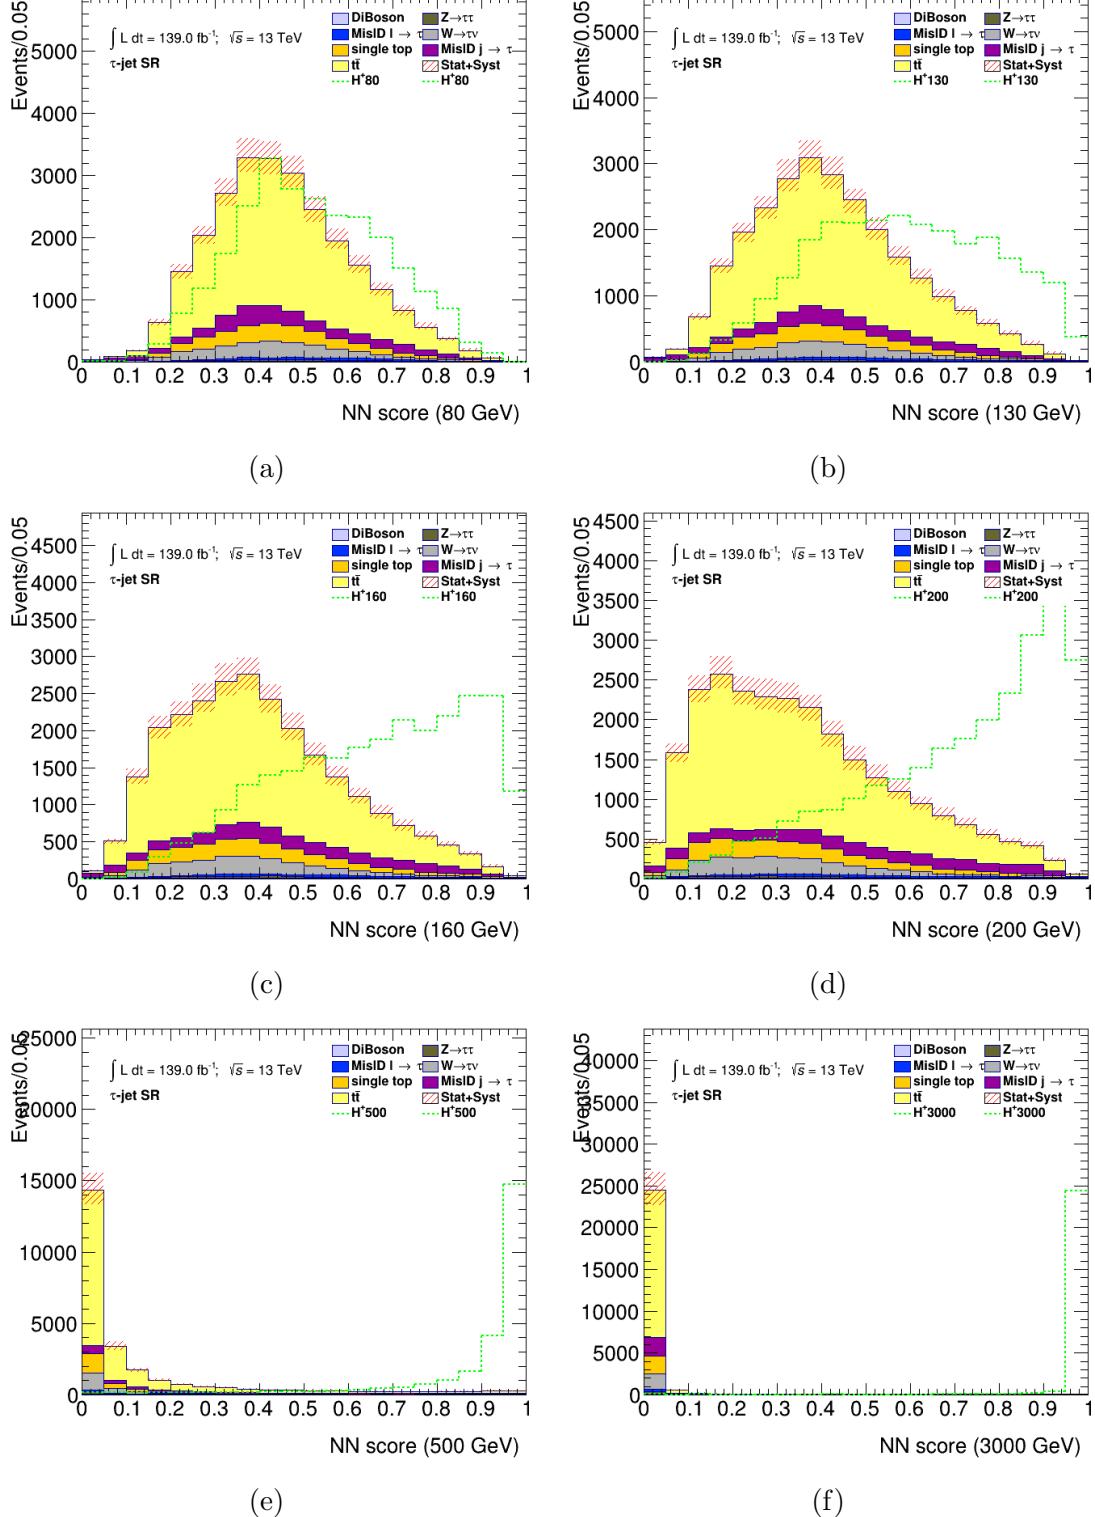

Figure 6.12: PNN score distributions in the signal region of the $\tau + \text{jets}$ channel, for the six charged Higgs boson mass parameters. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty bands include all statistical and systematic uncertainties. The normalization of the signal (shown for illustration) corresponds to the integral of the background.

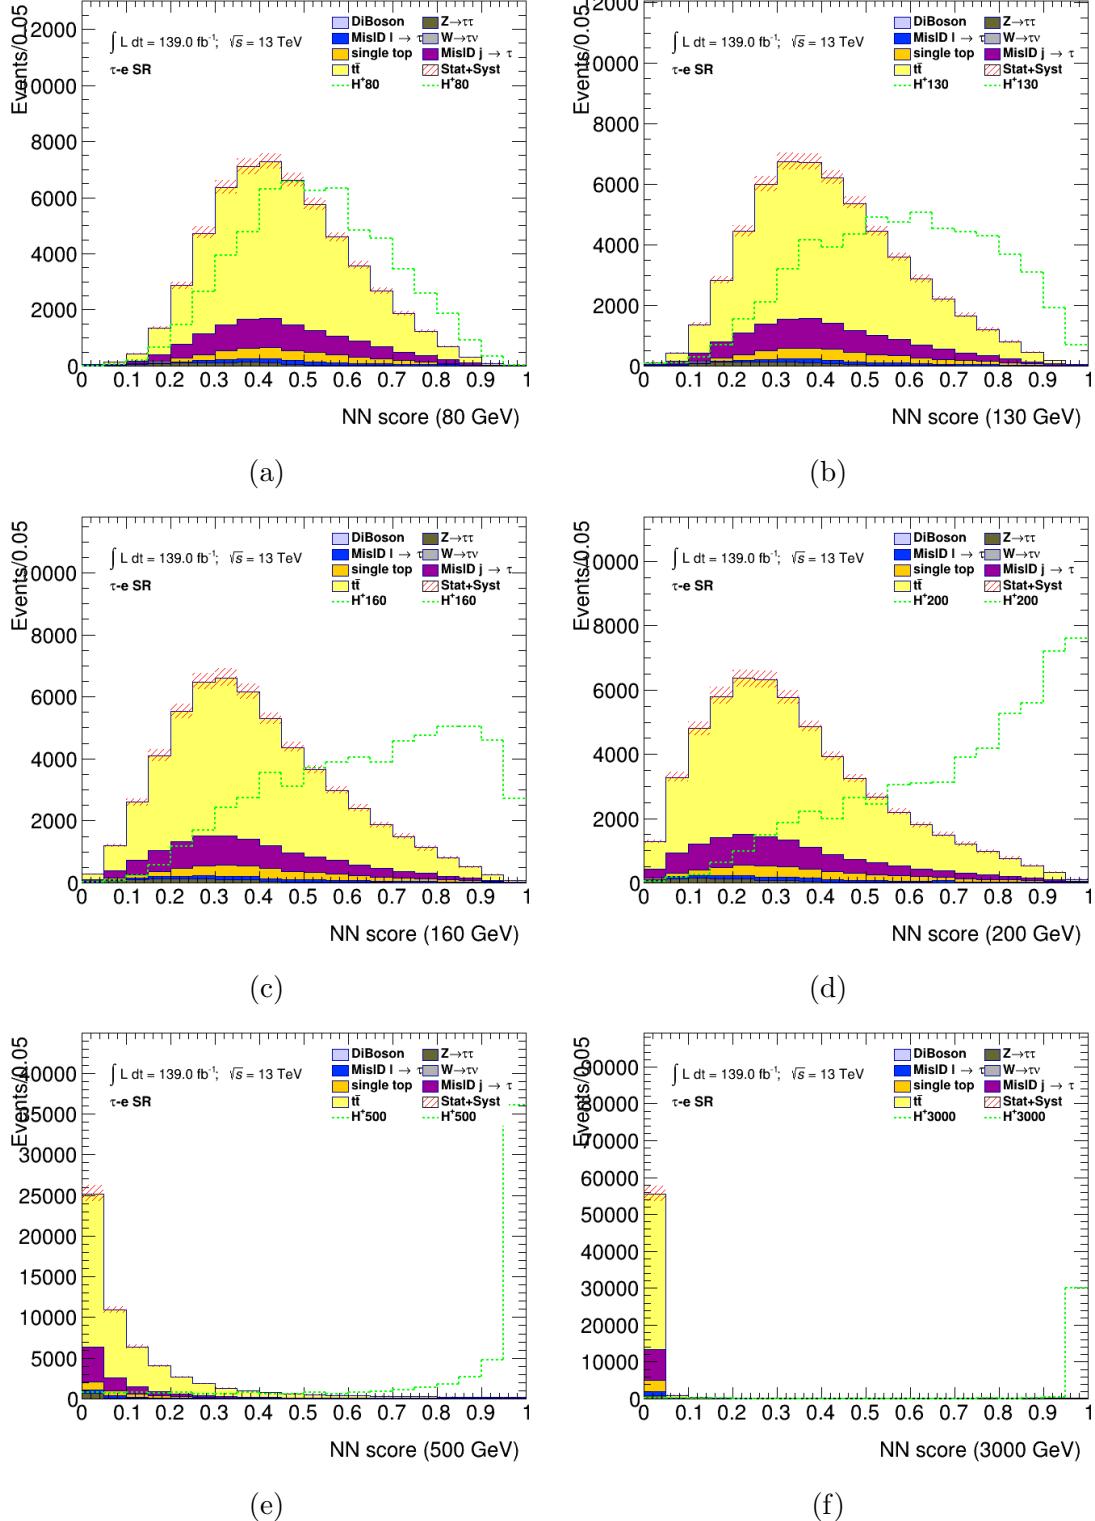

Figure 6.13: PNN score distributions in the signal region of the $\tau+e$ sub-channel, for the six charged Higgs boson mass parameters. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty bands include all statistical and systematic uncertainties. The normalization of the signal (shown for illustration) corresponds to the integral of the background.

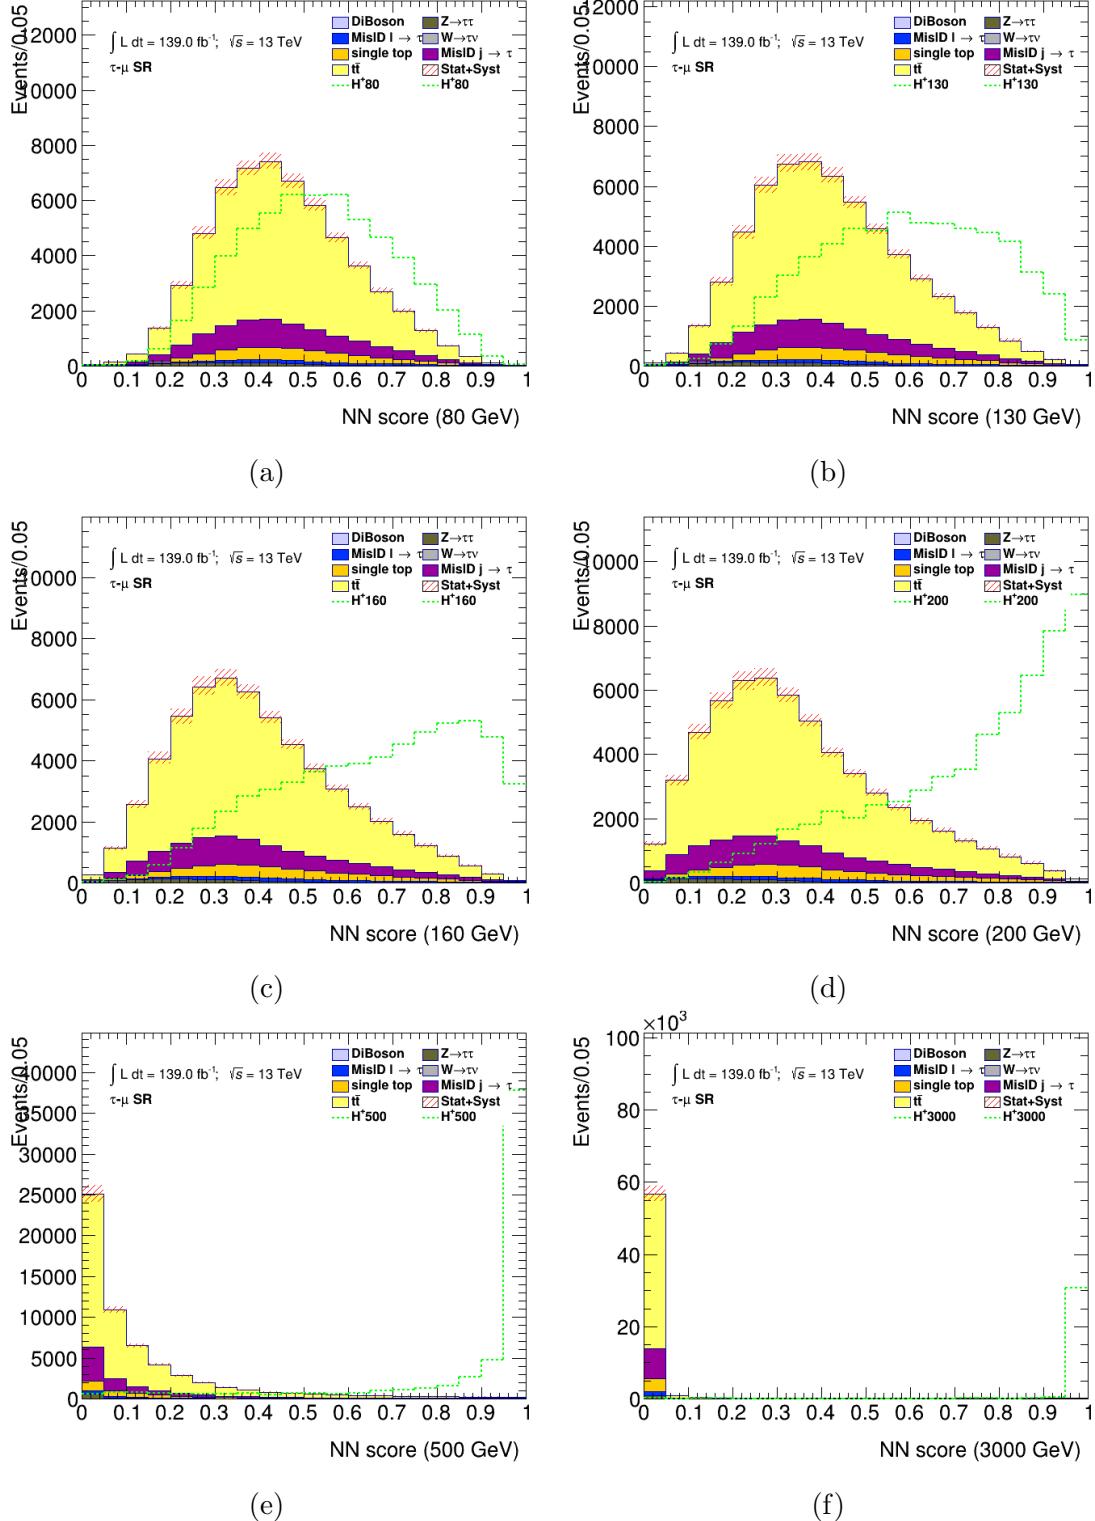

Figure 6.14: PNN score distributions in the signal region of the $\tau + \mu$ sub-channel, for the six charged Higgs boson mass parameters. The lower panel of each plot shows the ratio of data to the SM background prediction. The uncertainty bands include all statistical and systematic uncertainties. The normalization of the signal (shown for illustration) corresponds to the integral of the background.

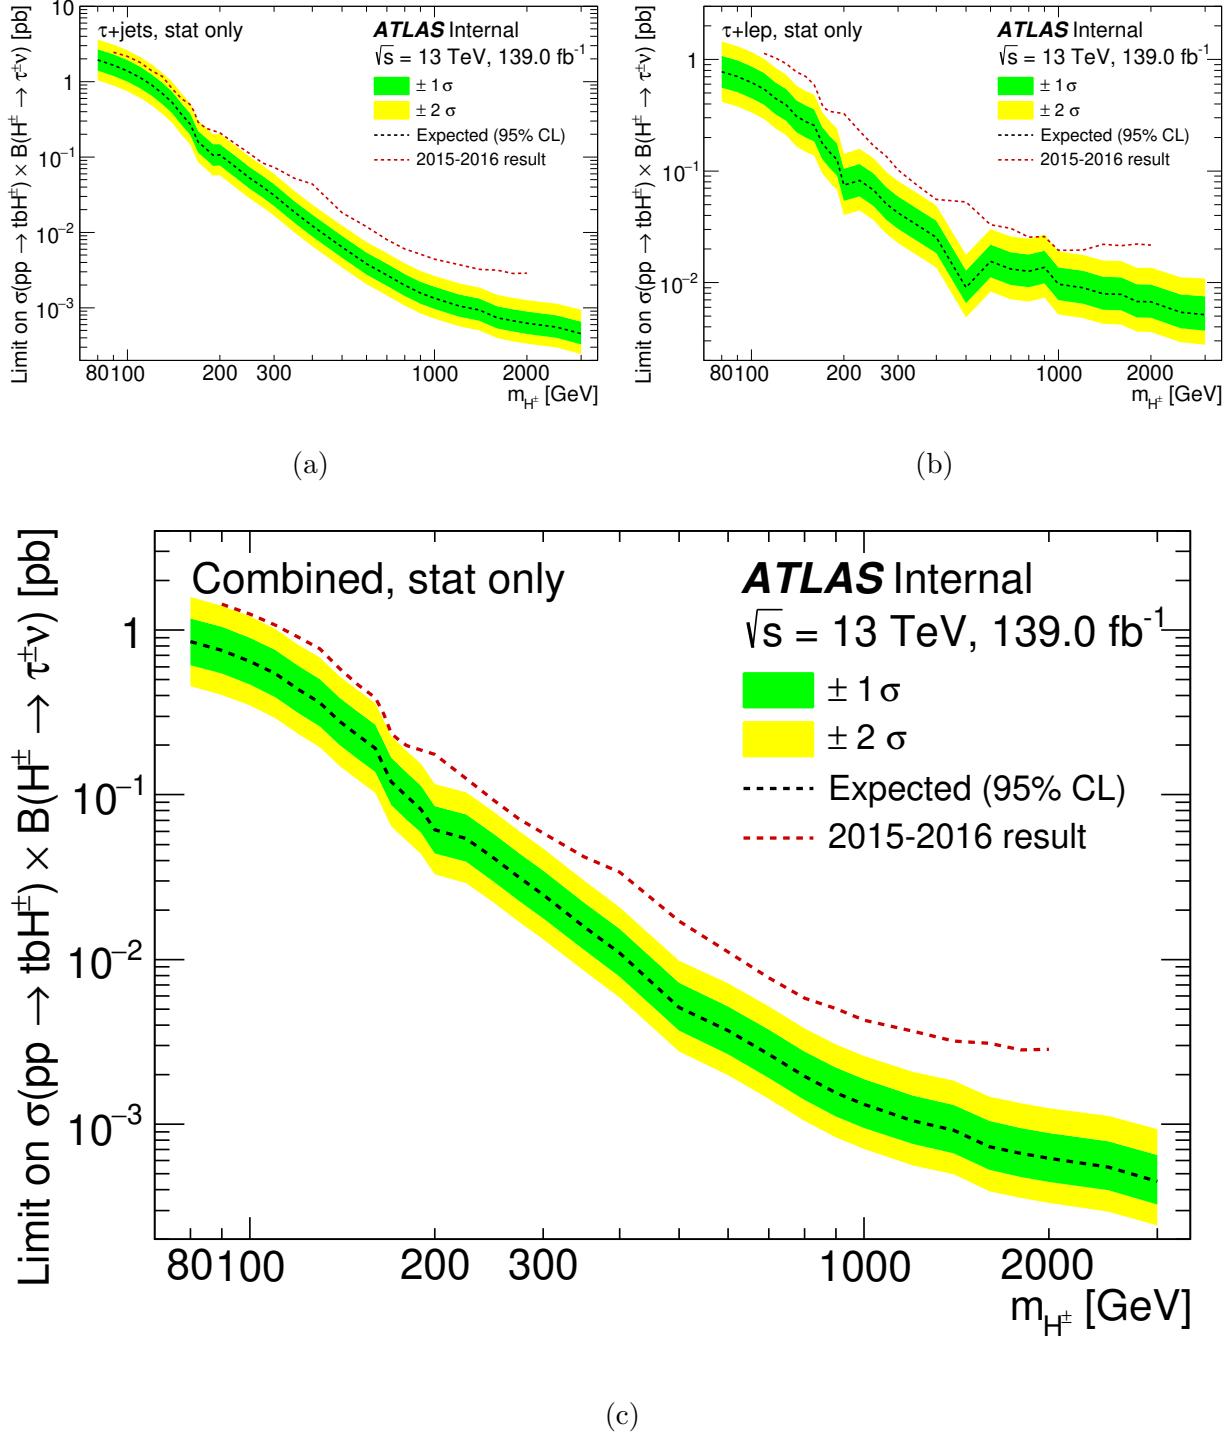

Figure 6.15: Expected 95% CL exclusion limits on $\sigma(pp \rightarrow tbH^\pm) \times \mathcal{B}(H^\pm \rightarrow \tau^\pm \nu)$ as a function of the charged Higgs boson mass in 139 fb^{-1} of pp collision data at $\sqrt{s} = 13 \text{ TeV}$ in the $\tau + \text{jets}$ signal region (a), $\tau + \ell$ signal region (b), and the combination of the $\tau + \text{jets}$ and $\tau + \ell$ signal regions (c). In the case of the expected limits, one- and two-standard-deviation uncertainty bands are also shown. As a comparison, the expected exclusion limits obtained with the dataset collected in 2015 and 2016 [8] are also shown.

CHAPTER 7

CONCLUSION

The Standard Model is an incredibly accurate model of fundamental particle physics, but is ultimately incomplete. There are many possible extensions to the Standard Model; this dissertation covers a search for a charged Higgs boson in the $H^\pm \rightarrow \tau^\pm \nu_\tau$ final state within the 2-Higgs Doublet Model (2HDM) theory.

The search consists of two subchannels based on the decay of the associated top quark; $\tau + \ell$ for the leptonic decay channel and $\tau + \text{jets}$ for the hadronic decay channel. Parameterized Neural Networks were investigated and optimized to separate signal from background in the Signal Regions. Assuming a result consistent with the SM expected results are shown compared to previously observed results. At the time of writing, the final unblinding procedure within the ATLAS collaboration is underway.

Appendices

APPENDIX A

TILECAL DATA QUALITY

This appendix gives an overview of the TileCal and ATLAS Data Quality Monitoring (DQM) systems. The author served as Data Quality (DQ) Co-Coordinator for a significant portion of their time in the Ph.D. program. During their tenure, it was their responsibility to verify the integrity and sign off on all physics data coming out of TileCal.

A.1 ATLAS Data Quality

The process of data collection with the ATLAS detector begins with an LHC fill. Each fill corresponds to injections of protons into the LHC in preparation for data taking. When the beams are collimated and focused, the LHC team declares a period of “stable beams”. At this point, the ATLAS team begins to ramp up the high voltage in the tracker and muon systems. Once the pixel preamplifiers are turned on, ATLAS declares “ready for physics”. Data collected by ATLAS is recorded against a six digit number referred to as a run number. Each run is subdivided into Luminosity Blocks (LBs), with each LB corresponding to 60 seconds of data taking. LBs provide a granularity for checking quality of data and sorting of data based on its quality.

A.2 Calibration Systems

To ensure the data being collected by TileCal is accurate and meets the required standards a series of calibration checks are performed with varying frequency. The systems used for calibration were designed to be built into the full detector; allowing calibration between physics data taking runs without requiring physical access to the detector. A diagram of the various calibration systems and where in the readout chain each calibration is done can be seen in Figure A.1.

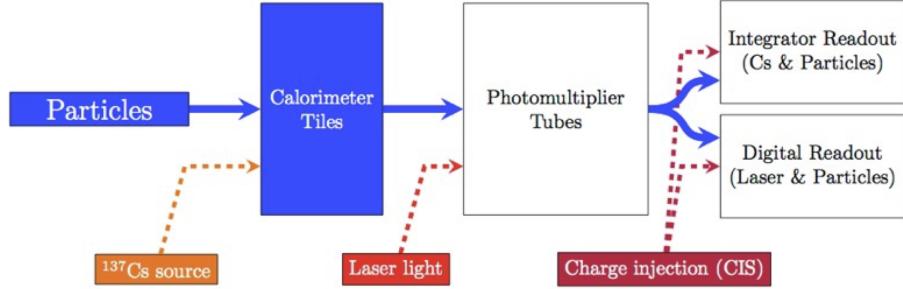

Figure A.1: TileCal calibration checks within the readout chain [20].

The cesium calibration system within TileCal is meant to calibrate the entire readout chain from scintillator to final digital signal readout. Several sources of CS_{137} are hydraulically moved throughout the detector. The cesium calibration was designed to be run once a month.¹ The laser calibration system measures the response of the PMTs with respect to the last cesium scan. Laser calibration can be done during empty bunches within the LHC fill and with dedicated calibration runs as well. The Charge Injection System (CIS) measures the response of digitizers and readout electronics by injecting controlled charges into the electronics. CIS calibration is done with dedicated calibration runs. The last calibration system is the minimum bias system, where physics signal is integrated over $\sim 10 - 20$ ms. Minimum bias calibration is used to fill in the gaps between cesium calibration scans. The average response variation for one cell from the laser, cesium, and minimum bias systems can be seen in Figure A.2.

¹Due to historical issues with leaking hydraulic fluid, the frequency of cesium scans was drastically reduced during Run-2.

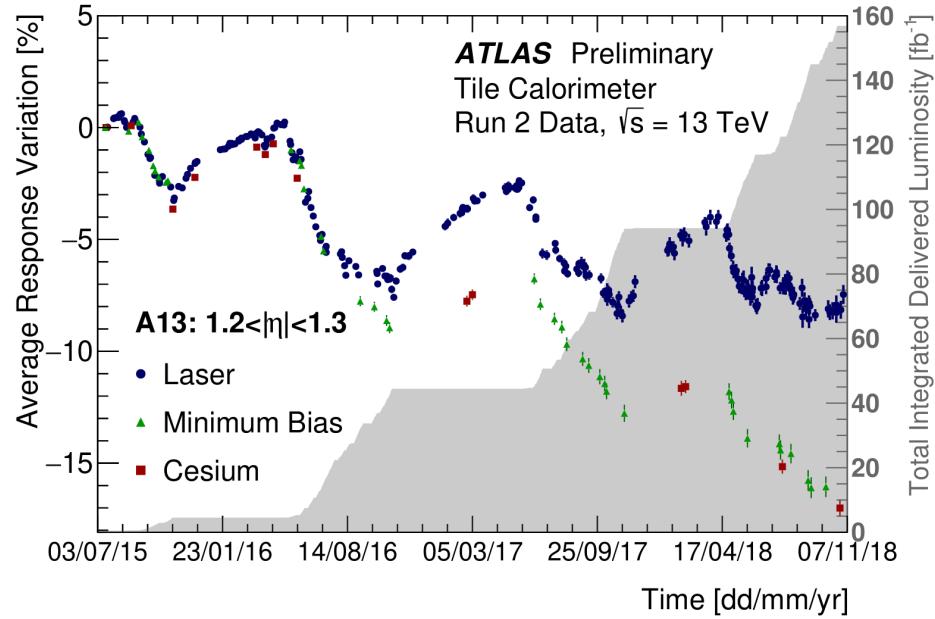

Figure A.2: Average response variation from the beginning of Run-2 of TileCal cell A13 is shown [60].

APPENDIX B

FAKE FACTORS

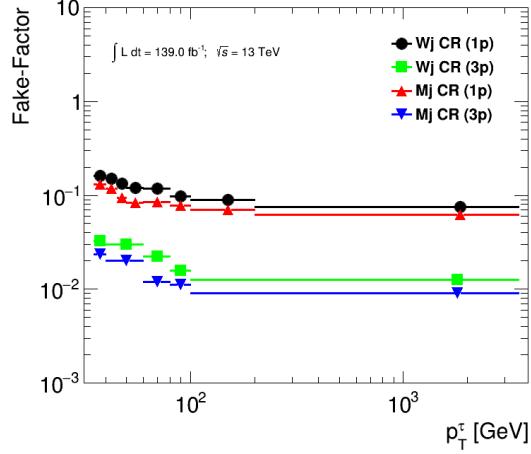

Figure B.1: Fake factors parameterized as a function of p_T^τ and the number of charged τ decay products (1-prong and 3-prong) obtained in the multi-jet and W+jets CRs. The errors shown represent the statistical uncertainty.

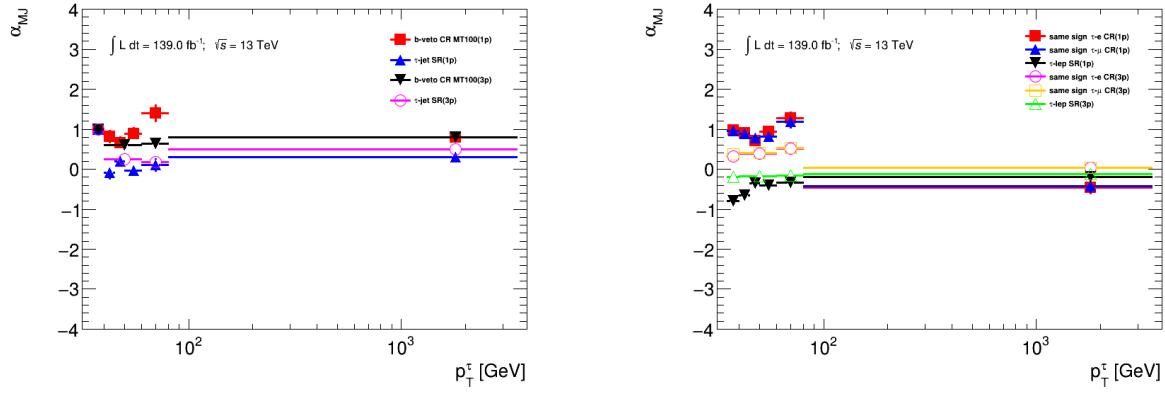

Figure B.2: Corrected α_{MJ} values for the $\tau_{had-vis} + \text{jets}$ b-veto $m_T > 100$ control region, $\tau_{had-vis} + \text{jets}$ signal region, $\tau_{had-vis} + \text{electron(muon)}$ with same-sign control region and the $\tau_{had-vis} + \text{lepton}$ signal region. Error bars represent uncertainties due to α_{MJ} fitting using template-fit method.

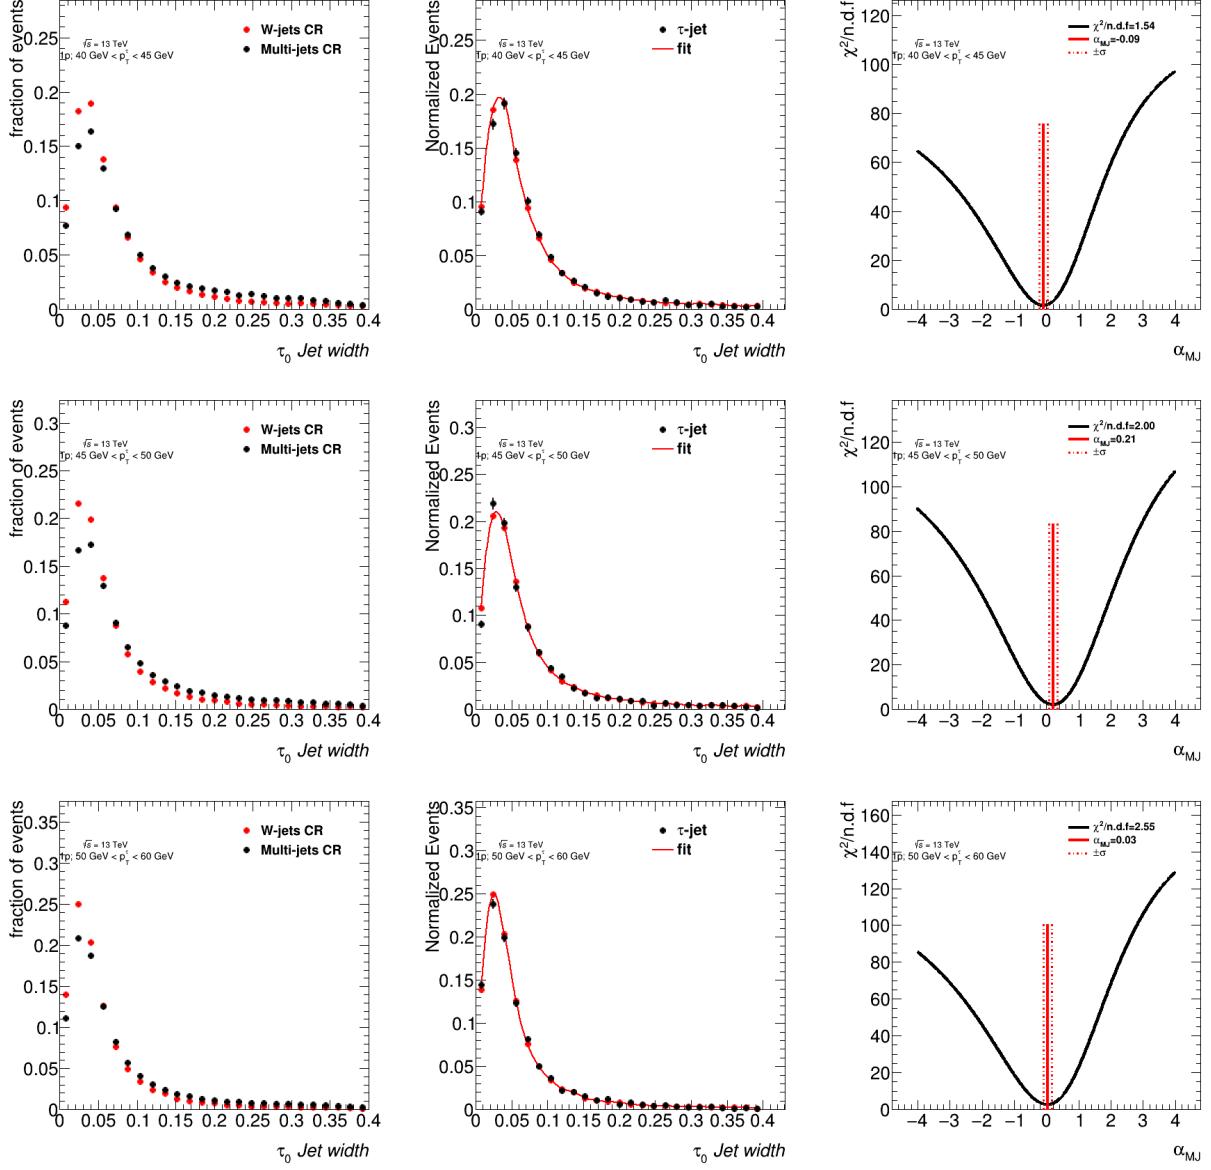

Figure B.3: Estimation of α_{MJ} in the $\tau_{\text{had-vis}} + \text{jets}$ signal region for $p_T \leq 60 \text{ GeV}$ 1-prong $\tau_{\text{had-vis}}$ candidates. Left: templates of discriminating variables for different $\tau_{\text{had-vis}}$ p_T and n-prong slices. Middle: shape of the discriminating variable obtained in the signal region and fitted shape using the templates measured in the control regions. Right: χ^2/ndf of the fit as a function of α_{MJ} , the error on α_{MJ} is defined by the band at $\chi^2_{\min}/\text{ndf} + \sqrt{\frac{2}{\text{ndf}}}$.

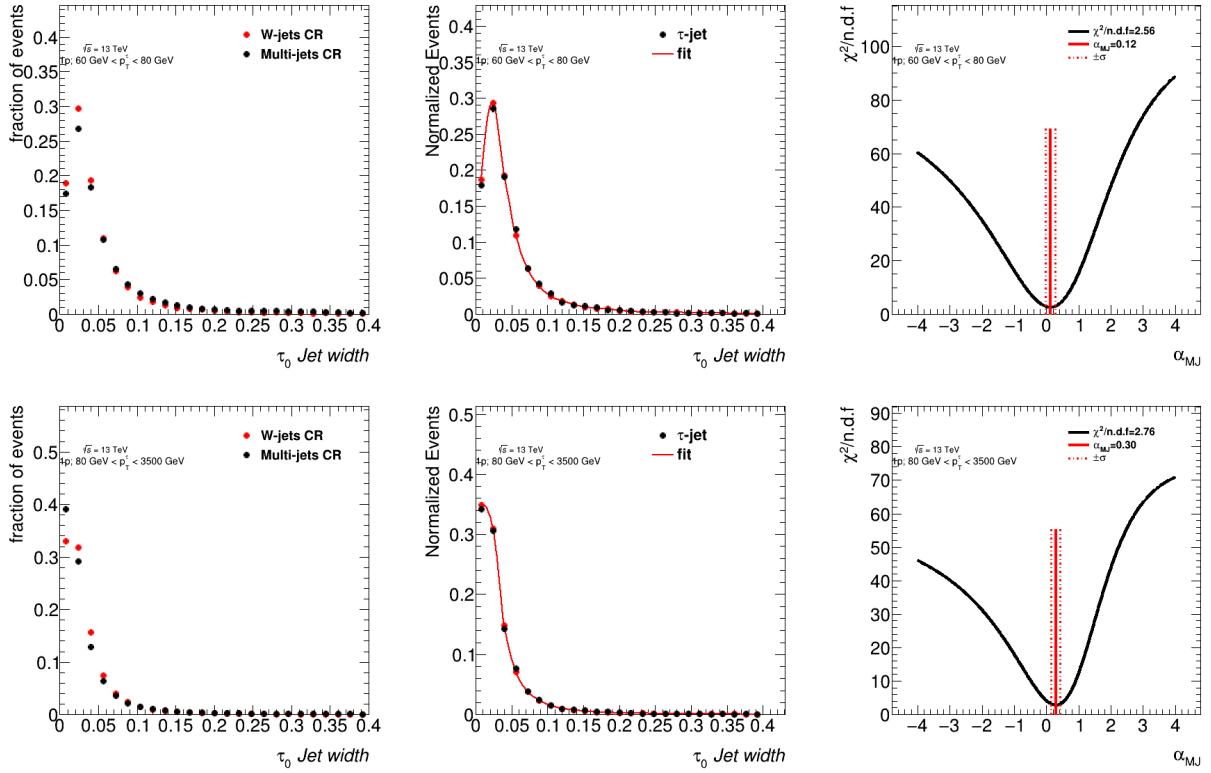

Figure B.4: Estimation of α_{MJ} in the $\tau_{had-vis} +$ jets signal region for $p_T \geq 60$ GeV 1-prong $\tau_{had-vis}$ candidates. Left: templates of discriminating variables for different $\tau_{had-vis}$ p_T and n-prong slices. Middle: shape of the discriminating variable obtained in the signal region and fitted shape using the templates measured in the control regions. Right: χ^2/ndf of the fit as a function of α_{MJ} , the error on α_{MJ} is defined by the band at $\chi^2_{\min}/\text{ndf} + \sqrt{\frac{2}{\text{ndf}}}$.

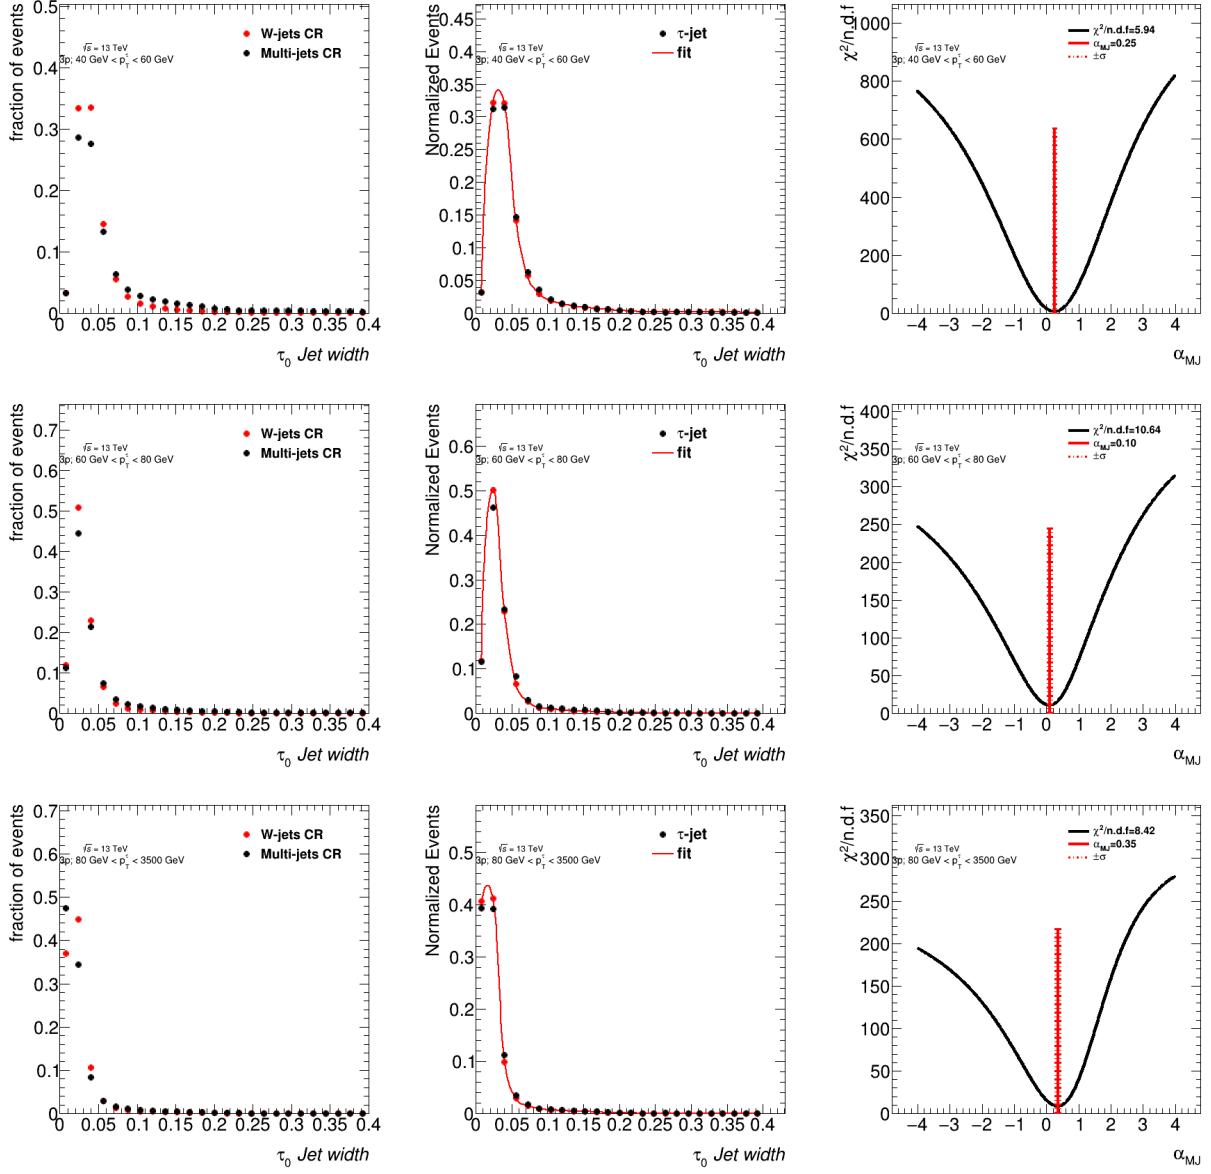

Figure B.5: Estimation of α_{MJ} in the $\tau_{\text{had-vis}} + \text{jets}$ signal region for 3-prong $\tau_{\text{had-vis}}$ candidates. Left: templates of discriminating variables for different $\tau_{\text{had-vis}}$ p_T and n-prong slices. Middle: shape of the discriminating variable obtained in the signal region and fitted shape using the templates measured in the control regions. Right: χ^2/ndf of the fit as a function of α_{MJ} , the error on α_{MJ} is defined by the band at $\chi^2_{\min}/\text{ndf} + \sqrt{\frac{2}{\text{ndf}}}$.

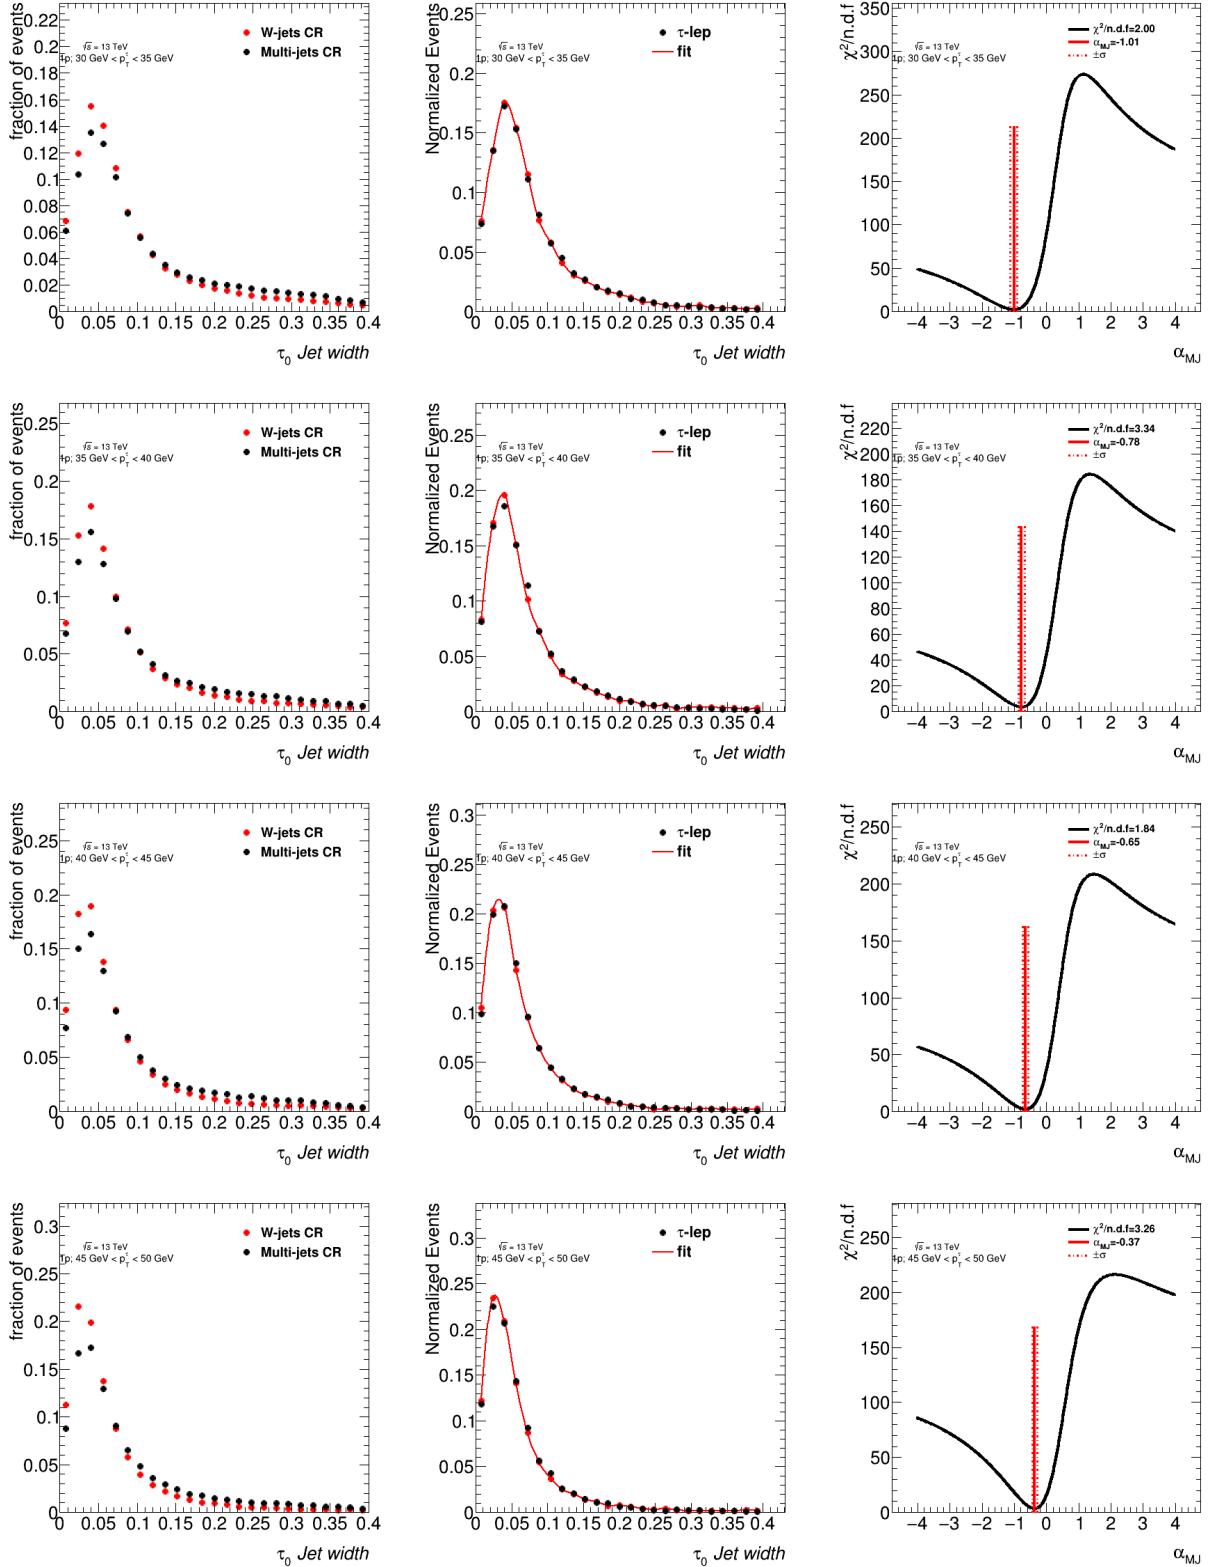

Figure B.6: Estimation of α_{MJ} in the $\tau_{\text{had-vis}} + \text{lepton}$ signal region for $p_T \leq 50 \text{ GeV}$ 1-prong $\tau_{\text{had-vis}}$ candidates. Left: templates of discriminating variables for different $\tau_{\text{had-vis}}$ p_T and n-prong slices. Middle: shape of the discriminating variable obtained in the signal region and fitted shape using the templates measured in the control regions. Right: χ^2/ndf of the fit as a function of α_{MJ} .

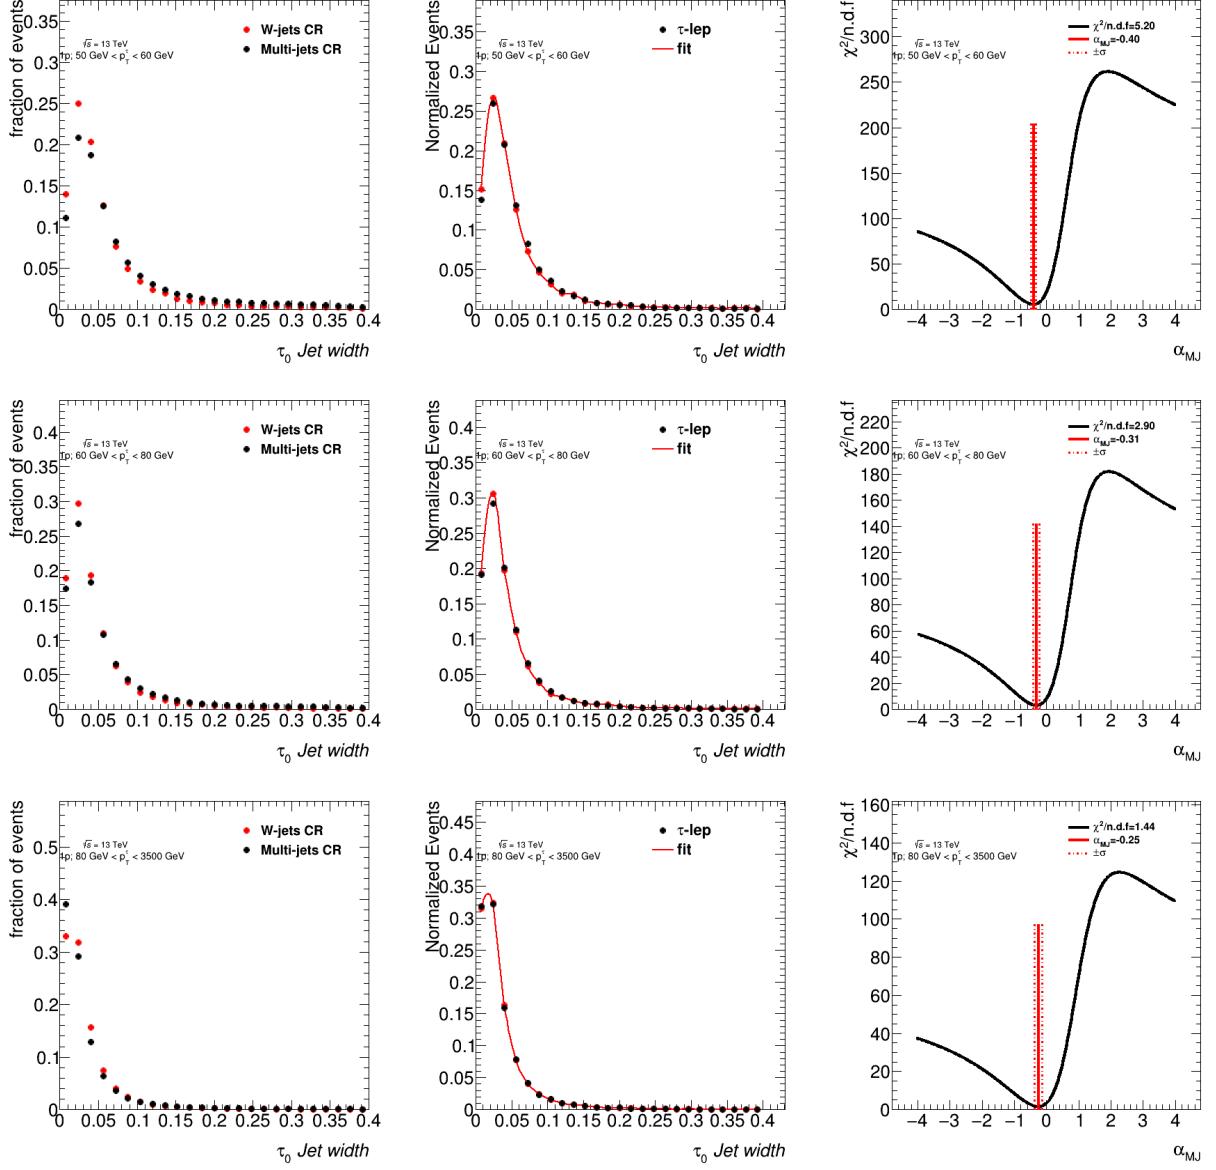

Figure B.7: Estimation of α_{MJ} in the $\tau_{\text{had-vis}} + \text{lepton}$ signal region for $p_T \geq 50 \text{ GeV}$ 1-prong $\tau_{\text{had-vis}}$ candidates. Left: templates of discriminating variables for different $\tau_{\text{had-vis}}$ p_T and n-prong slices. Middle: shape of the discriminating variable obtained in the signal region and fitted shape using the templates measured in the control regions. Right: χ^2/ndf of the fit as a function of α_{MJ} , the error on α_{MJ} is defined by the band at $\chi^2_{\min}/\text{ndf} + \sqrt{\frac{2}{\text{ndf}}}$.

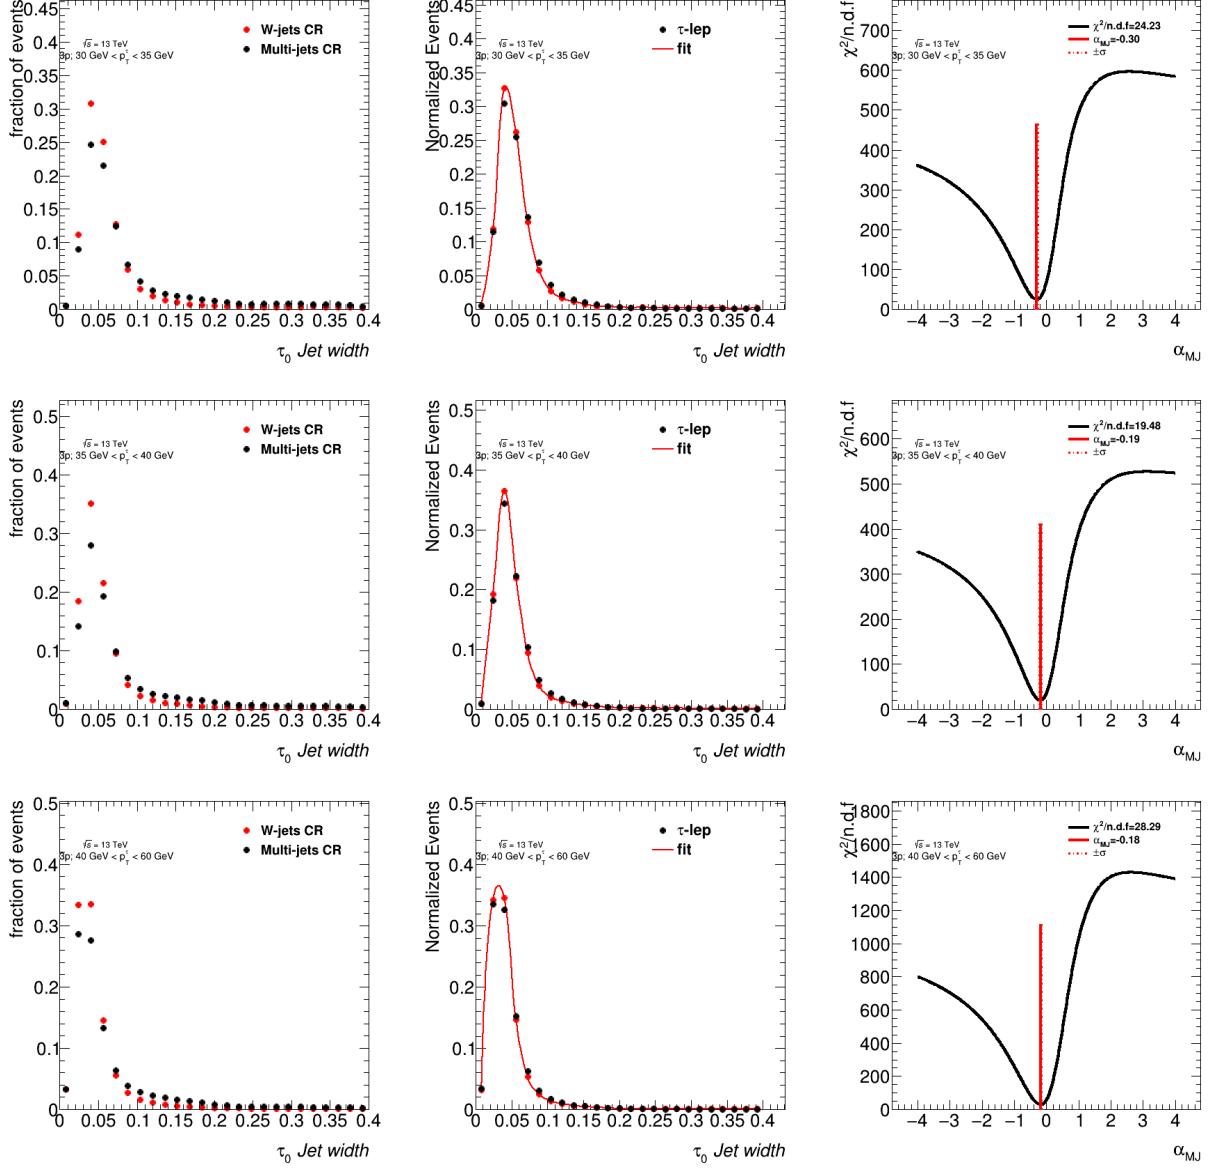

Figure B.8: Estimation of α_{MJ} in the $\tau_{\text{had-vis}} + \text{lepton}$ signal region for $p_T \leq 60 \text{ GeV}$ 3-prong $\tau_{\text{had-vis}}$ candidates. Left: templates of discriminating variables for different $\tau_{\text{had-vis}}$ p_T and n-prong slices. Middle: shape of the discriminating variable obtained in the signal region and fitted shape using the templates measured in the control regions. Right: χ^2/ndf of the fit as a function of α_{MJ} , the error on α_{MJ} is defined by the band at $\chi^2_{\min}/\text{ndf} + \sqrt{\frac{2}{\text{ndf}}}$.

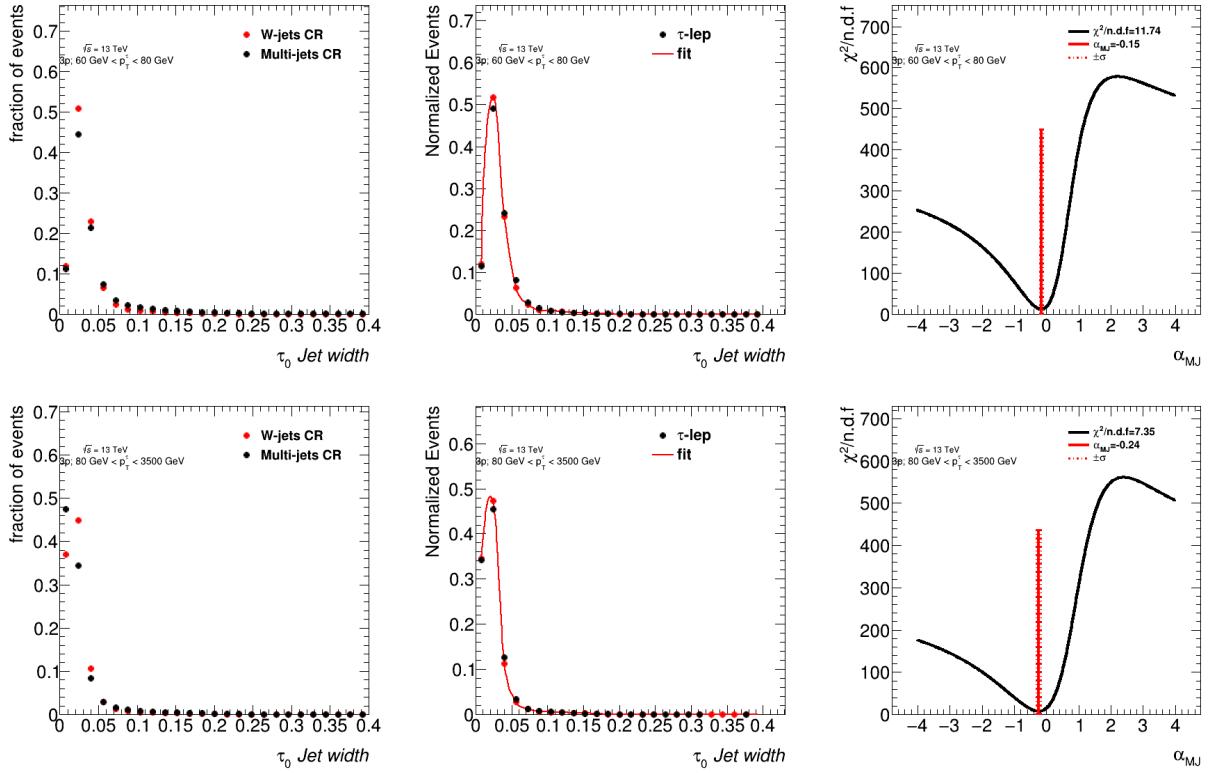

Figure B.9: Estimation of α_{MJ} in the $\tau_{\text{had-vis}} + \text{lepton}$ signal region for $p_T \geq 60 \text{ GeV}$ 3-prong $\tau_{\text{had-vis}}$ candidates. Left: templates of discriminating variables for different $\tau_{\text{had-vis}}$ p_T and n-prong slices. Middle: shape of the discriminating variable obtained in the signal region and fitted shape using the templates measured in the control regions. Right: χ^2/ndf of the fit as a function of α_{MJ} , the error on α_{MJ} is defined by the band at $\chi^2_{\min}/\text{ndf} + \sqrt{\frac{2}{\text{ndf}}}$.

APPENDIX C

ADDITIONAL VALIDATION PLOTS

C.1 $\tau+\text{jets}$ Validation Plots

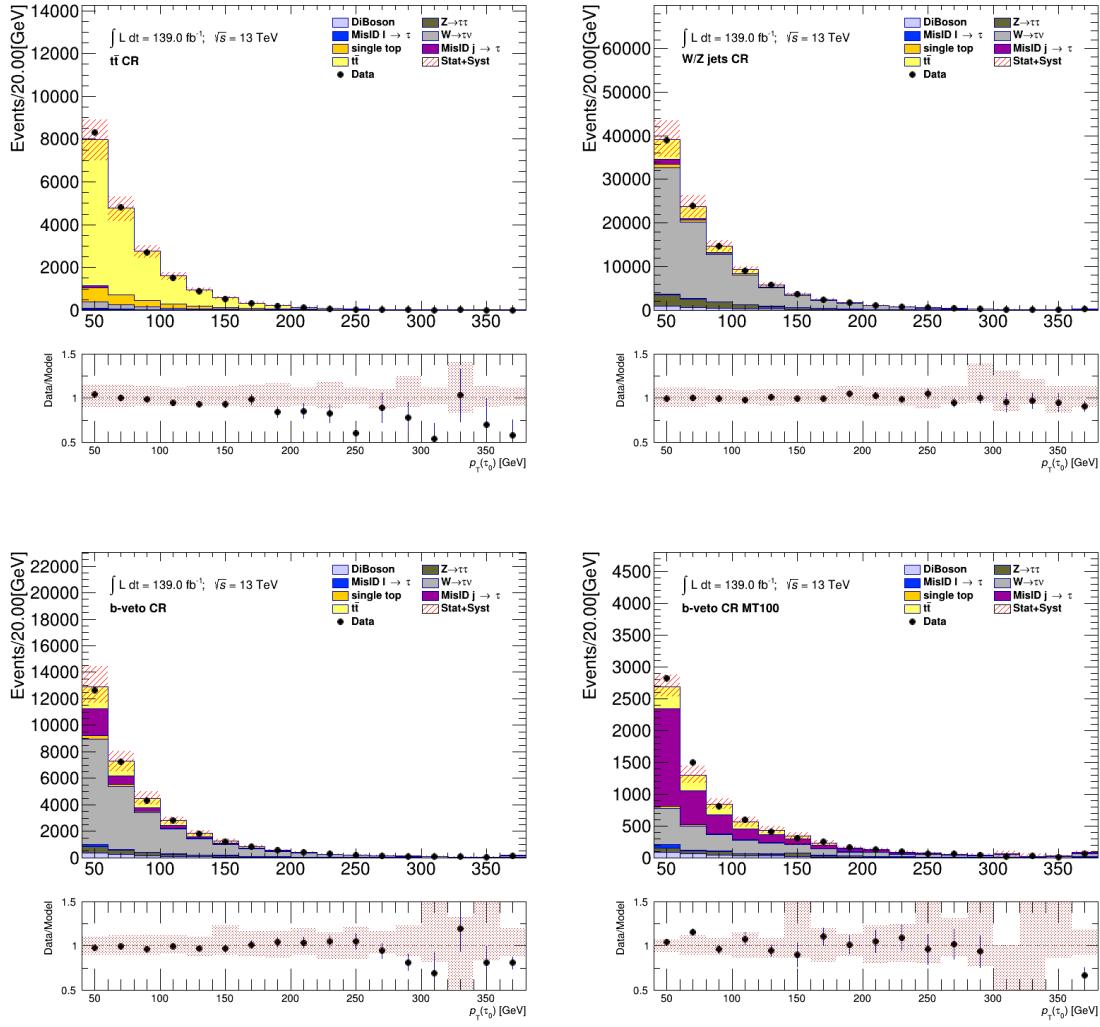

Figure C.1: Comparison between the predicted and the measured p_T^τ distributions in various control regions defined for the $\tau+\text{jets}$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

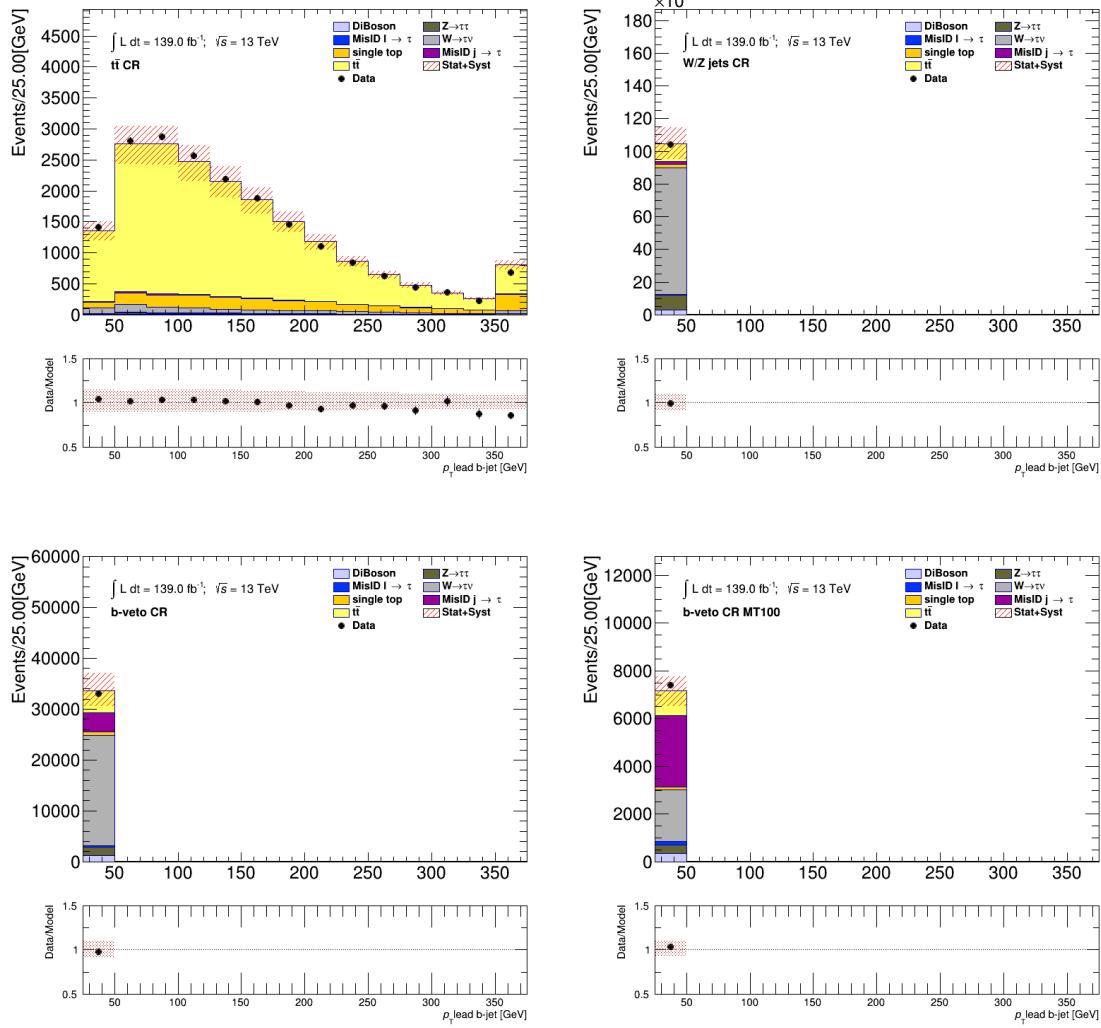

Figure C.2: Comparison between the predicted and the measured p_T^{b-jet} distributions in various control regions defined for the $\tau + \text{jets}$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

C.2 $\tau + \ell$ Validation Plots

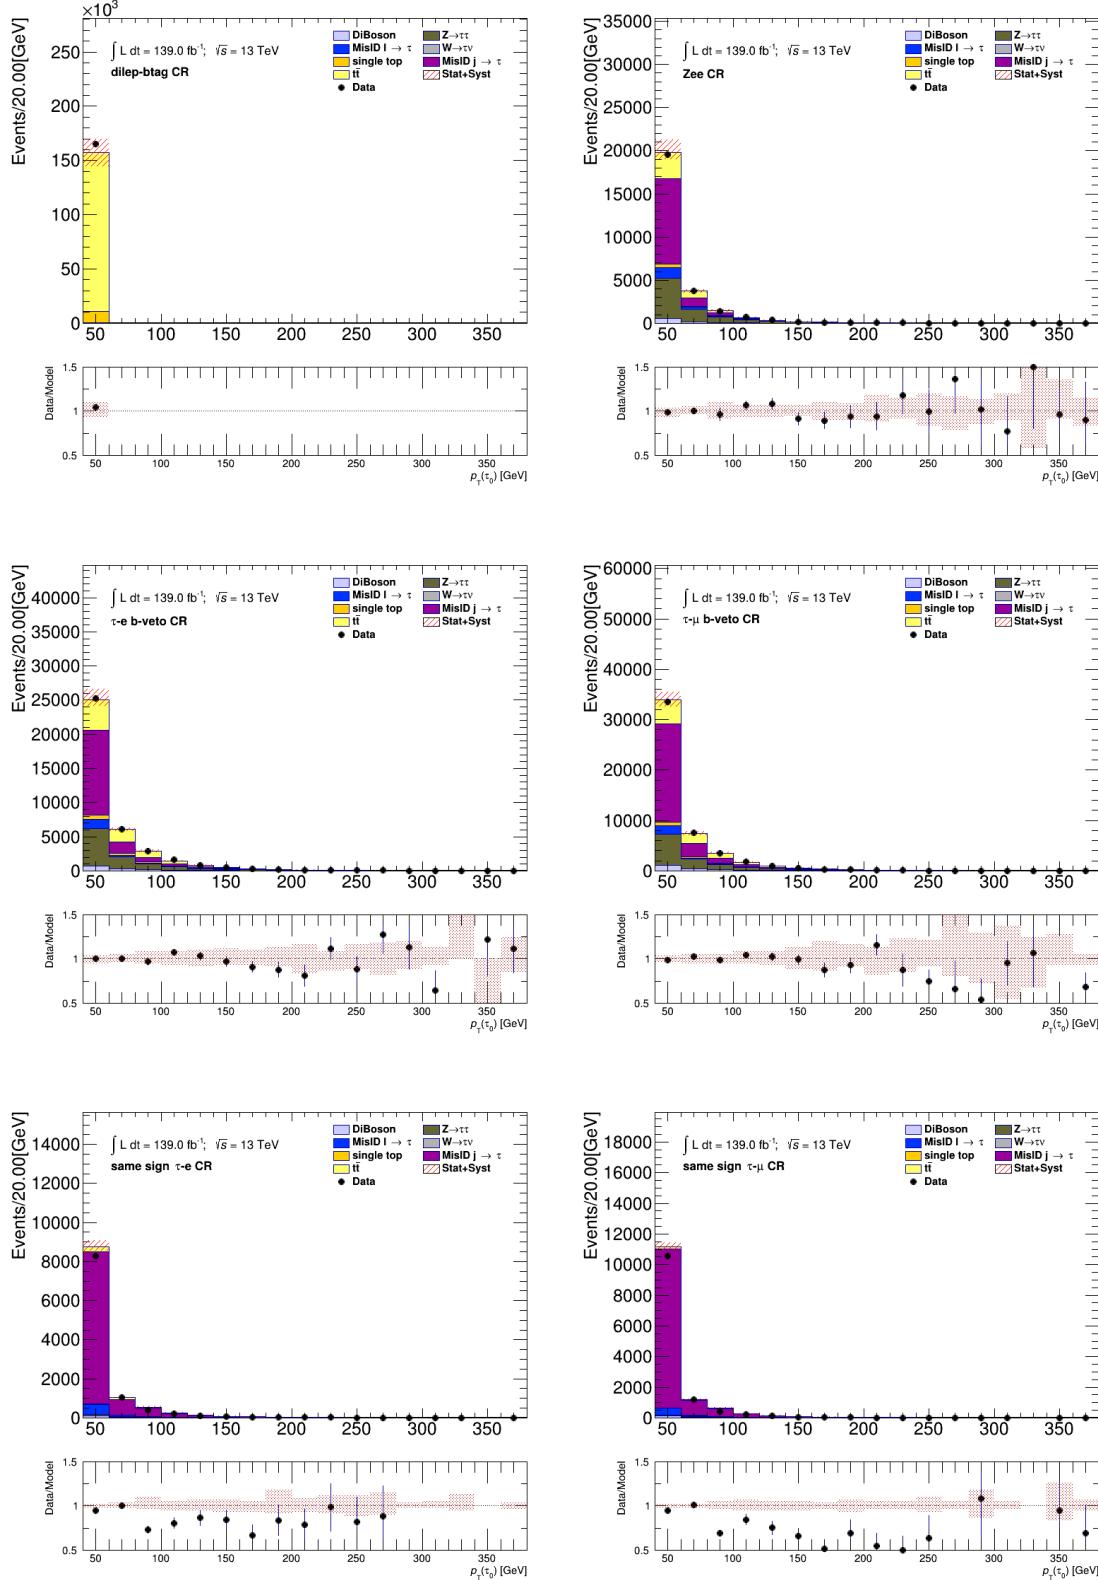

Figure C.3: Comparison between the predicted and the measured p_T^τ distributions in various control regions defined for the $\tau + \ell$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

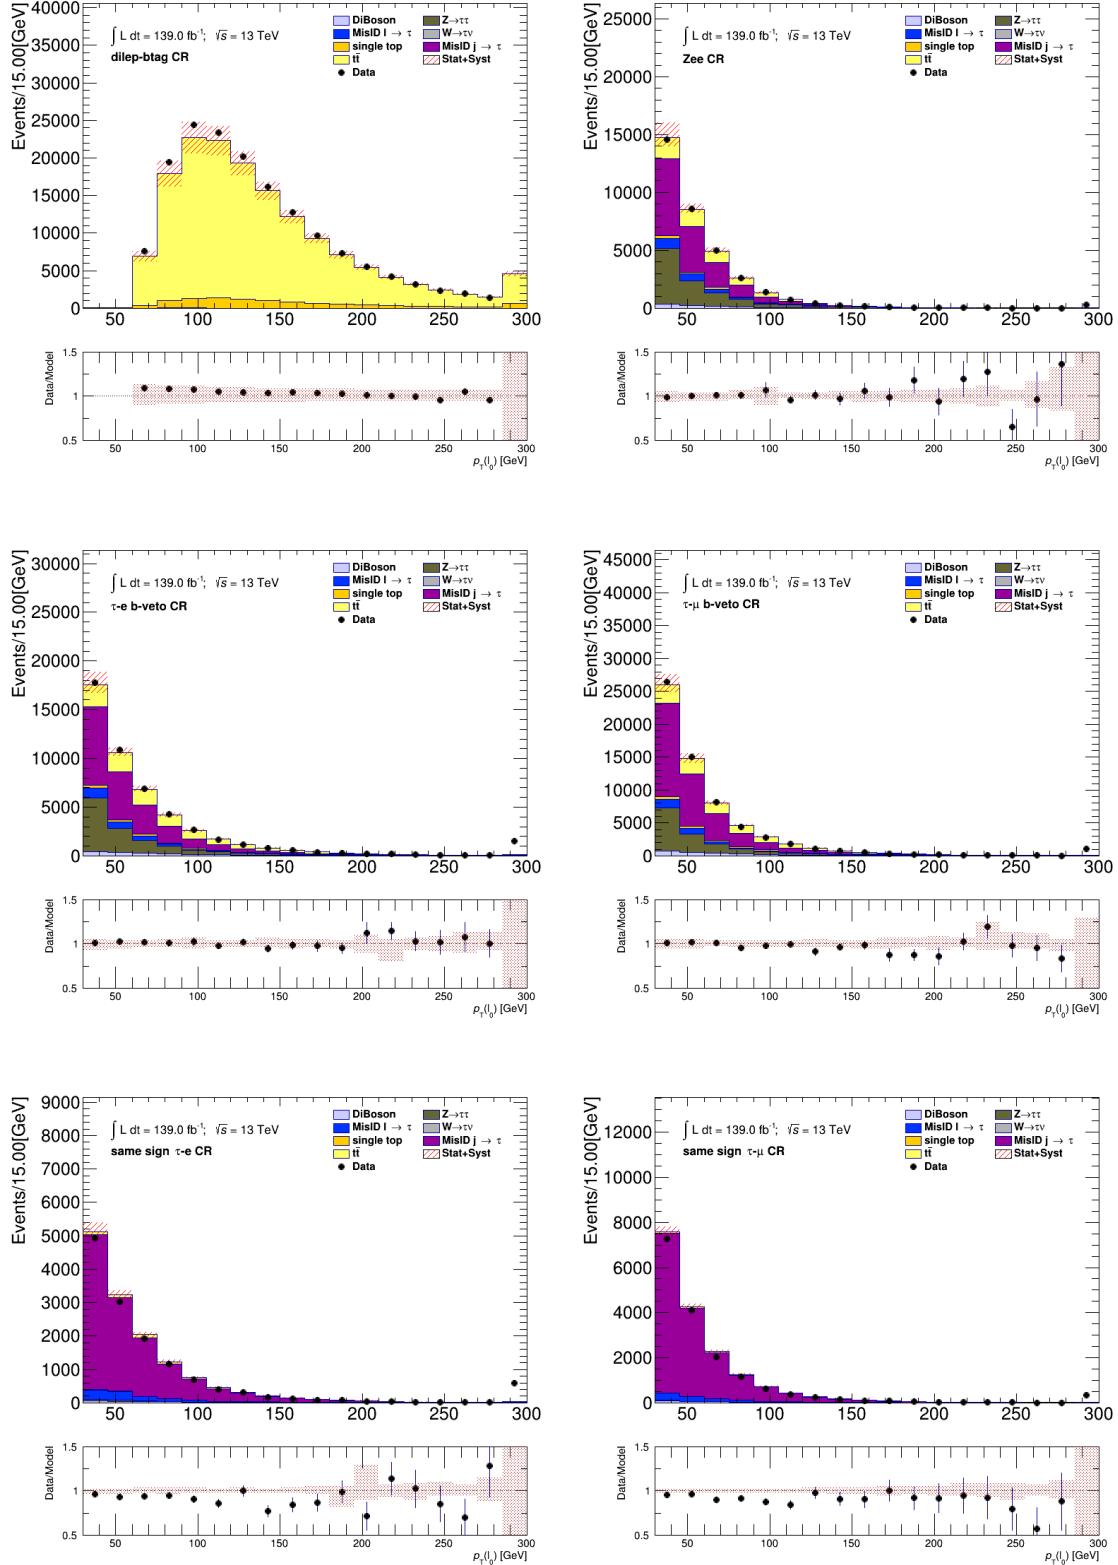

Figure C.4: Comparison between the predicted and the measured p_T^ℓ distributions in various control regions defined for the $\tau + \ell$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

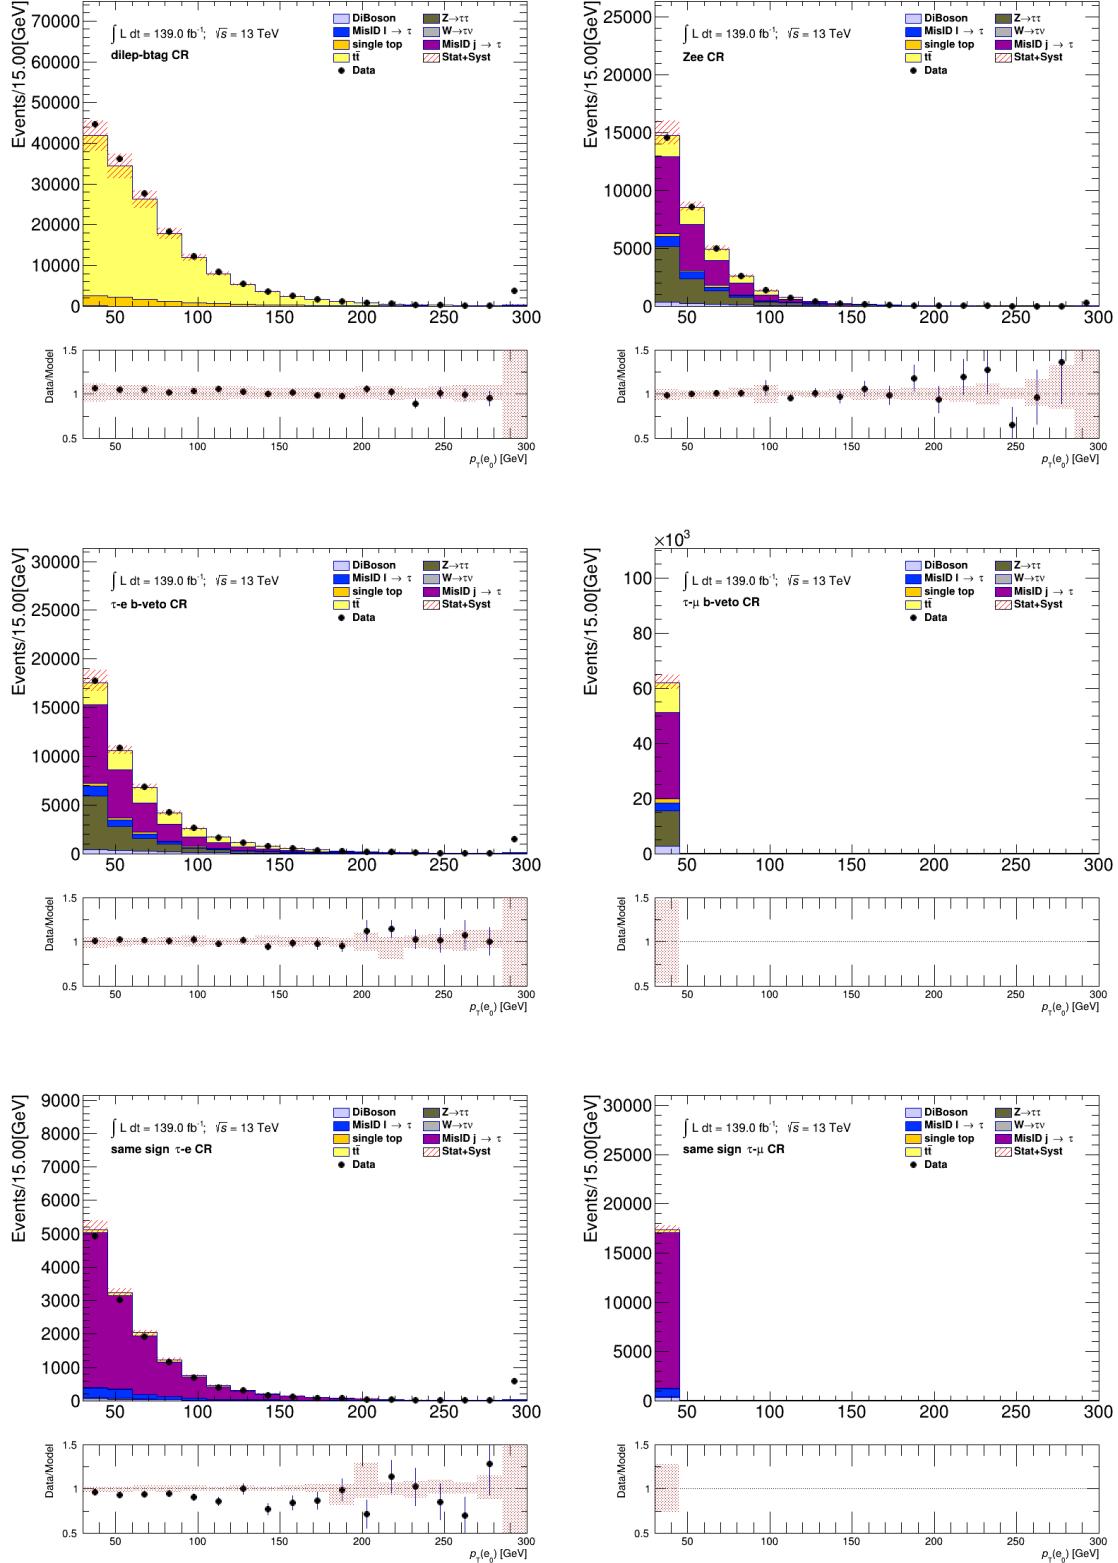

Figure C.5: Comparison between the predicted and the measured p_T^e distributions in various control regions defined for the $\tau + \ell$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

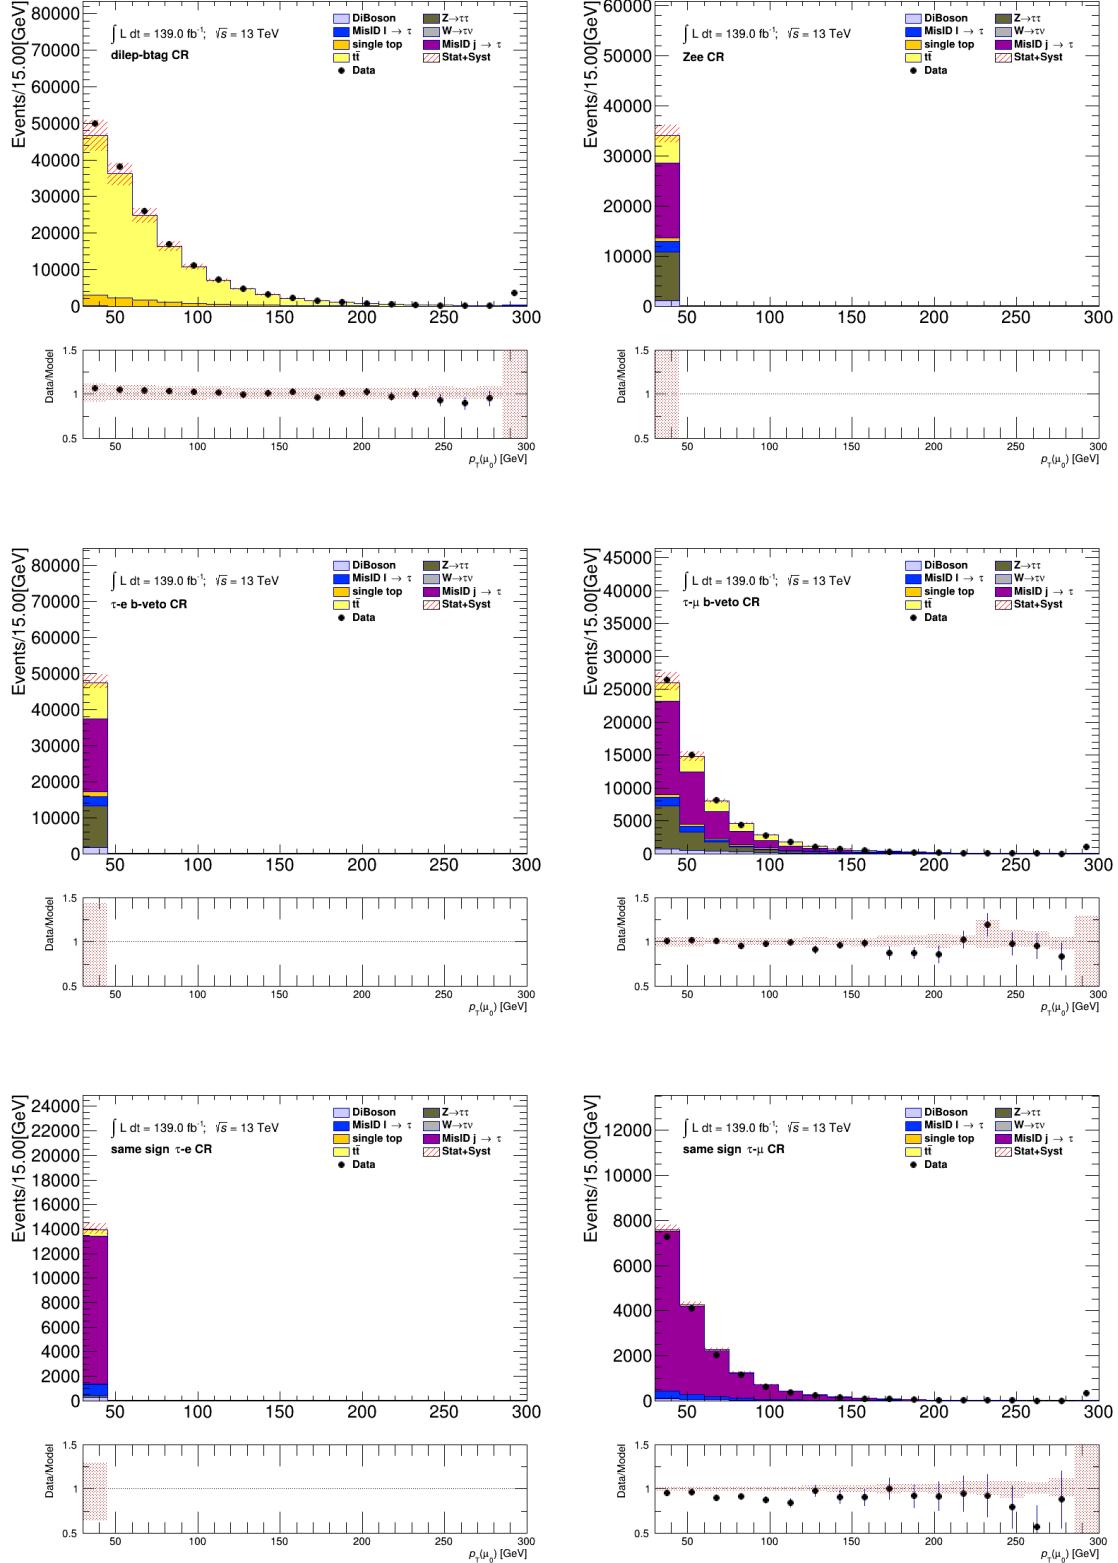

Figure C.6: Comparison between the predicted and the measured p_T^μ distributions in various control regions defined for the $\tau + \ell$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.

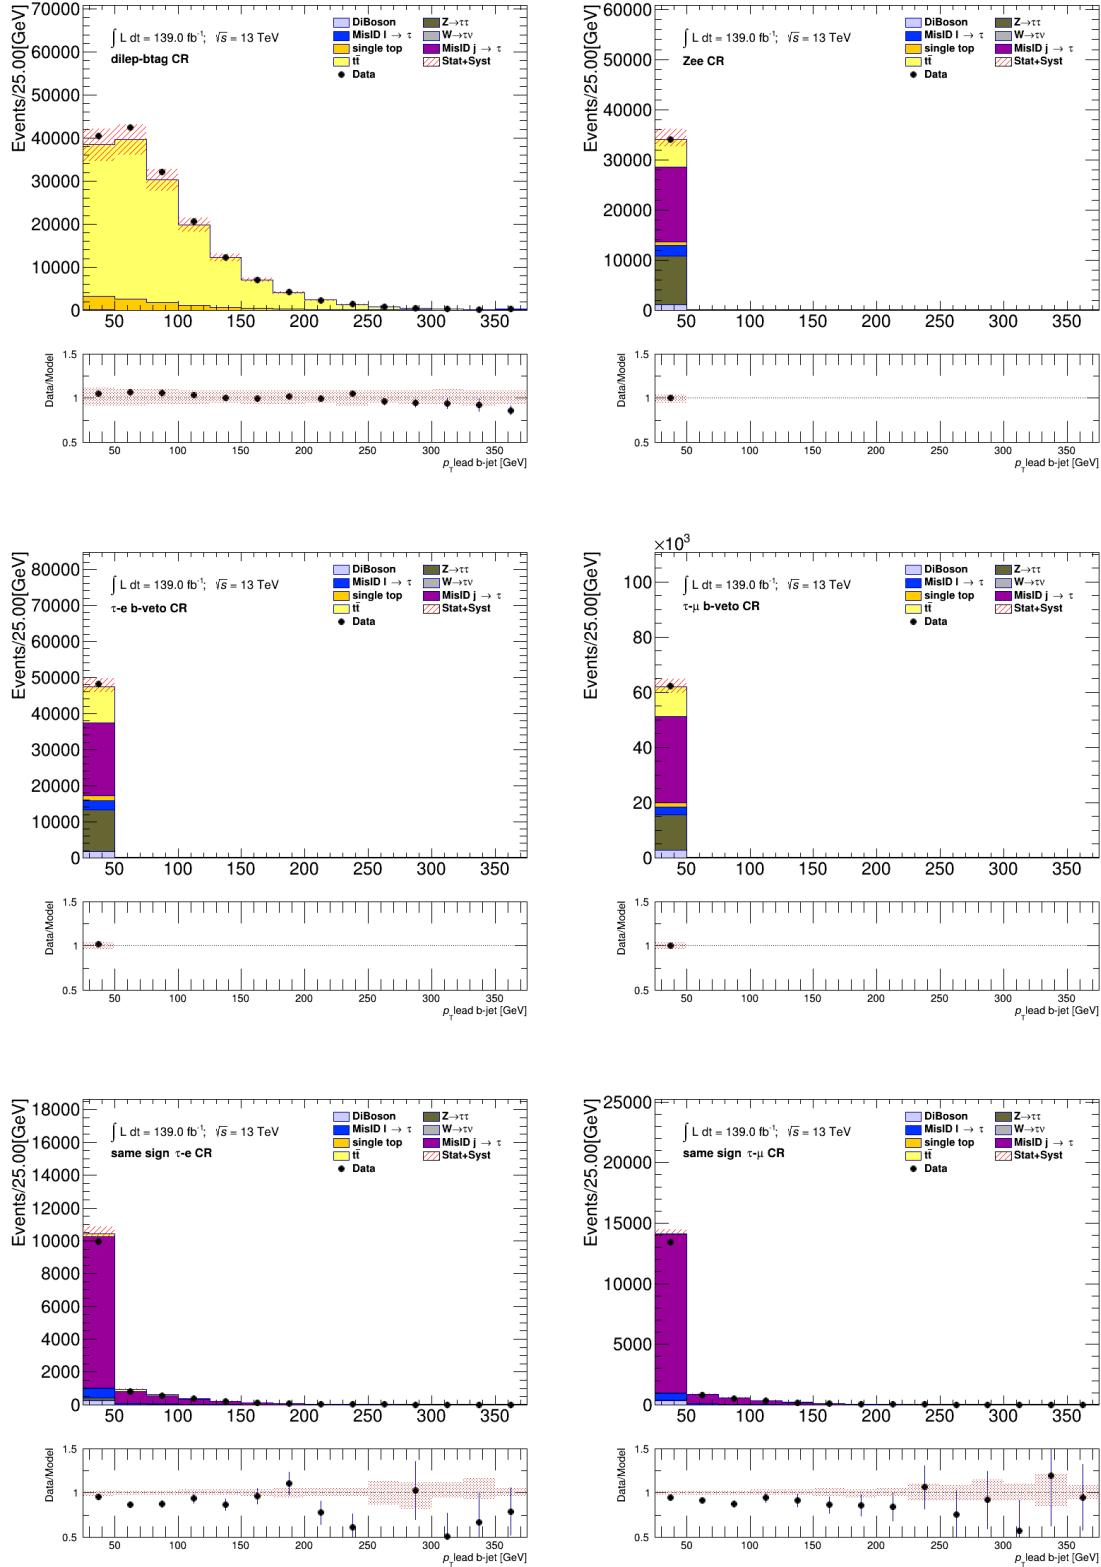

Figure C.7: Comparison between the predicted and the measured $p_T^{b\text{-jet}}$ distributions in various control regions defined for the $\tau + \ell$ channel. The uncertainty band includes both statistical and systematic uncertainties on the background prediction.
